Foreword

Rocket propellants are hugely important members of the larger group of energetic materials. This continuously developing field requires knowledge and understanding of a wide-range of compounds from the highly reactive fluorine and nitrogen oxides, to organic alkylboranes and alcohols. For rocket propulsion, it is essential that accurate information on the physical and chemical properties of the chemicals involved has been determined precisely and can be relied upon. This is not only the case for known rocket propellants, but is equally essential for developing new, “greener” (less toxic) propellants for the future. The demands on rocket propellants are continuously developing and changing with time, as new needs and requirements for satellites and rockets emerge. Therefore, the *Encyclopedia of Rocket Propellants* is an essential resource for understanding current and past rocket propellants, as well as for designing those for the future. A collection of the vast physical and chemical data for past, present and modern rocket propellant systems has been missing, and it is essential that a source is available in which all reliable data has been collected together and presented in a clear and informative manner.

Amongst the many ways to categorize propellants for chemical rockets, they can be separated into two groups, namely, solid propellants or liquid propellants, with the former being subdivided into double-base or composite propellants. Liquid propellants can be subdivided into monopropellants or bipropellants, the latter of which can be again subdivided into hypergolic or nonhypergolic. Therefore, the complexity of these systems is self-evident. Hydrazine and the methylated derivatives methylhydrazine (MMH) and unsymmetrical dimethylhydrazine (UDMH) in combination with nitric acid or dinitrogen tetroxide are currently the most widely-used hypergolic propellants, however, hydrazine and its methylated derivatives are not only toxic, but also carcinogenic in test animals, and therefore it is of considerable importance to find less-toxic and non-carcinogenic alternatives which can still form hypergolic mixtures. Properties of many candidates in this context are summarized in this book. However, many more promising alternatives need to be found for the future. Despite the harmful properties of “traditional” rocket propellants such as MMH or UDMH, or the highly corrosive WFNA and RFNA, they continue to be used, while safer and more energetic alternatives are sought for the future.

Searching for new, environmentally friendly and/or increased performance rocket propellants requires knowledge of a large and diverse number of chemical compounds, many of which are not easy to handle. Despite this, since the publication of the book *Raketentreibstoffe* (Springer) in 1968 by the same author as this

encyclopedia, no other such comprehensive and detailed book has been published on rocket propellants making the *Encyclopedia of Rocket Propellants* a seminal work for past, present and future developments in this area.

Prof. Dr. Thomas M. Klapötke
Department of Chemistry
Ludwig-Maximilians University
Munich, Germany

Preface

Encyclopedia of Oxidizers

This is the first set of a series of sets in the *Encyclopedia of Rocket Propellants* summarizing the existing literature on rocket propellants, both liquid and solid rocket propellants. The first set, *Encyclopedia of Oxidizers*, contains information on both liquid and solid oxidizers. The second set to be released shortly after, *Encyclopedia of Liquid Fuels*, is a summary of literature on liquid fuels. The differentiation between liquid fuels and solid fuels was necessary because solid fuels usually are the binders for solid propellants, a topic reserved for a future, planned set in this series. The third set, *Encyclopedia of Monopropellants*, will be a very comprehensive summary of the chemistry of monopropellants. The fourth and fifth sets, planned for the coming years, will describe the performance of hypergolic and nonhypergolic bipropellant combinations, usually combinations of oxidizers and fuels. If time permits, future sets will eventually deal with various aspects of solid propellants, such as “Composite Solid Propellants” and “Double-Base Solid Propellants”, and they would also include gas generants which have found numerous industrial applications such as in airbag inflators in automobile occupant passive restraint systems. “Hybrid Propellants” may find a home in a future set in the distant future.

In spite of the increased capabilities of online search engines like Google Scholar, the current sets of books will be an indispensable tool for scientists and engineers in the rocket propulsion industry and research organizations. The hazards of working with rocket propellants need to be well understood.

Our *Encyclopedia of Rocket Propellants* book series will be the preferred reference source for future generations of rocket propellant chemists. When referring to the profession of rocket propellant chemists, this should not be done without quoting, tongue-in-cheek, the preface written by I. Asimov for J. D. Clark’s landmark book *Ignition!*:

“Now it is clear that anyone working with rocket fuels is outstandingly mad. I don’t mean garden-variety crazy or a merely raving lunatic. I mean a record-shattering exponent of far-out insanity.”

The reader will notice, though, that the correct terminology should have been “rocket propellants” and not just “rocket fuels”. The author of the current book feels that this quote from the literature adequately describes the risks involved for chemists involved with developing more energetic rocket propellants and explosives. The dividing line between powerful rocket propellants and potential explosives is very narrow and rocket propellant development is often treading on a narrow path. Nevertheless, this is one of the most exciting branches of chemistry to be involved with. It is the

chemistry of rocket propellants that has enabled the dramatic advances in space technology, with many benefits to the common consumer.

Reviewing the recent literature on rocket propellants and other energetic materials, one will notice that the increased capabilities of modern computers have enabled chemists to predict the performance of new molecules even before these compounds were ever made and tested in the laboratory. Numerous publications referenced in our books deal just with theoretical explorations of this type, and that is a difference to previous book publications on this subject.

Rocket propellants generally consist of oxidizers and fuels. The term “rocket fuels” is often misused to describe rocket propellants in general. Correct use of the term “rocket fuel” would only apply to the combustible, fuel-rich part of a propellant combination. Oxidizers for liquid rocket propellants are generally subdivided by physical properties and/or by reactivity. So we differentiate between storable and non-storable (usually cryogenic) propellants. When looking at the reactivity of hypergolic combinations, it is more often the oxidizer and not the fuel that determines if the resulting combination is self-igniting on contact or not. When listing combinations of rocket propellants, we always list the oxidizer first. This is because the properties and the activity of the oxidizer determine the nature of the combination more so than properties of the fuel would. There are fewer oxidizers than fuels in our inventory, so it is easier to organize book chapters on rocket propellant combinations first by arranging them by oxidizers and later by fuels.

A frequently used alternate term for oxidizer, mostly in biologic systems, is *oxidant*. This term is used mostly in life sciences and less frequently in the world of rocket propellants. When conducting literature searches, it may be advisable to search for both terms. A less frequently used term for propellant is *propellent*. And again, when doing literature searches, one may want to search for both variations of the spelling.

About the Format of the Several Sets in the Encyclopedia of Rocket Propellants

The manuscript for the *Encyclopedia of Rocket Propellants* has evolved through several iterations and modifications, and the terminology in designating sets, volumes, chapters, and sections has changed during this period. The most recent terminology is now referring to *Encyclopedia of Oxidizers* as a set of five volumes and similarly referring to *Encyclopedia of Liquid Fuels* as a set of five volumes. The sequence of volumes in a set and the sequence of chapters in a volume is arranged in alphabetical order, similar to a dictionary.

A critical reviewer might describe the format of the books as not much more than an annotated bibliography. The author is aware of the fact that collecting and reproducing references from the literature is not a very creative job, but to arrange these thousands of references in a systematic manner requires a good understanding of the subject matter, justifying the effort especially in the age of computers and the internet.

Fifty years ago it used to be common practice to cite literature references followed by their Chemical Abstract citation. Providing the Chemical Abstracts citation often allowed the reader to read a more detailed abstract and to decide if it is worthwhile to obtain a complete copy of the original publication. Nowadays that function has been taken over by Digital Object Identifiers (DOI) in the Internet. Nevertheless, we have continued to carry along a few Chemical Abstract citations in addition to the DOI. Some of those citations are useful because they direct users to the Chemical Abstracts Registry Number which can be used for subsequent, more specific searches in computerized data bases. Some of the books on energetic materials even contain an index of Chemical Abstract Registry Numbers.

Selection of Oxidizers

When selecting combinations of bipropellants, hypergolic or nonhypergolic, it is usually the oxidizer that determines the reactivity of the combination once oxidizer and fuel meet in the rocket engine combustion chamber. The choice of oxidizers has less of an impact on the specific impulse than the choice of fuels with their widely varying hydrogen content. The selection of oxidizers is governed by a number of considerations:

- Specific impulse
- Reactivity with the intended fuel partner (hypergolic or nonhypergolic?)
- Boiling point/critical point temperature
- Storage stability
- Density (important for compact, pressure-fed systems)
- Corrosivity (corrosive oxidizers require exotic materials for tankage and tubing)
- Toxicity
- Availability
- Cost

The same criteria apply also to the selection of fuels.

Until the beginning of the Space Age, liquid oxygen and fuming nitric acid had been used most extensively, primarily because of low cost and relatively easy handling characteristics. In the field of moderate performance, red fuming nitric acid had proved successful with proper modifications for dealing with its corrosive nature and pressure build-up problem of WFNA during storage. For high performance, liquid oxygen has been used satisfactorily, although additional engineering complications arise because of the need for refrigeration and/or insulation. Among the storable oxidizers, hydrogen peroxide and dinitrogen tetroxide have once been considered as close competitors to red fuming nitric acid. In the group of oxidizers containing fluorine, liquid fluorine has generally the highest performance. Nonmetallic fluorides have lower performance, but they are storable at room temperature. A common disadvantage of all

the compounds in this group of fluorine oxidizers stems from the fact that elemental fluorine is required for the industrial production of many of these oxidizers. The main disadvantage is the toxicity of the exhaust, hydrogen fluoride. Therefore fluorine oxidizers are now a thing of the past, and we include them here only because of historical interest. Outside the field of rocketry, fluorine and some nonmetal fluorides are still used for chemical lasers.

For solid oxidizers, ammonium perchlorate is the most widely used solid oxidizer. A detailed chapter in *Encyclopedia of Oxidizers* deals with ammonium perchlorate. Other solid oxidizers, actually used or evaluated for future use, are ammonium nitrate, ammonium dinitramide, hydrazinium salts, and hydroxylammonium salts, each represented with their own chapter.

An apology is needed to explain the incorrect display of semipolar bonds in nitro groups. Semipolar bonds are currently shown as N=O double bonds instead of semipolar bonds. Semipolar bonds should have been shown as an arrow $N \rightarrow O$. The chemical formula drawing software used here for creating chemical structures did not have an option for semipolar bonds, so for the time being these bonds were shown as double bonds instead.

Alkyl Perchlorate Esters

It is not because alkyl perchlorate esters are very important that they ended up in this prominent location in the first chapter of the *Encyclopedia of Oxidizers*; it happened because the chapters are now arranged in alphabetical order, and the letter A, of course, comes first in the alphabet.

Many organic energetic materials do not fit into the oxidizer category because they are underoxidized. Other energetic materials are not suitable as monopropellants because they are solids. These organic solid materials may be discussed in later volumes on solid propellant additives. Solid propellant additives can be energetic materials or they can be nitrogen-rich additives that are often added as coolants to solid gas generators.

Alkyl perchlorates and alkyl difluoroamino compounds have some similarities, and both types of compounds have been considered as rocket propellants, but their notorious shock sensitivity prevented any further development.

Alcohols will form esters with many acids. If acids carry oxygen, i.e., if they are oxyacids, the resulting esters may be of interest as rocket propellants. Esters of carboxylic acids are not suitable as rocket propellant oxidizers. Some are used as plasticizers in solid propellants. The oxyacids of interest are primarily those with nitrogen or chlorine as the central atom. Alkyl nitrites and alkyl nitrates will be discussed in later chapters. Alkyl perchlorates are the subject of this chapter. While in the realm of solid propellants (more accurately, composite solid propellants) solid inorganic perchlorates occupy a dominant position, liquid organic perchlorates have not gained much (if any) importance in the realm of liquid propellants. Those who had once worked with alkyl perchlorates in the laboratory later said that they “would not want to touch them again with a ten-foot pole.”

Alkyl perchlorates are mostly of theoretical interest. The theoretical advantage of alkyl perchlorates RCIO_4 over alkyl nitrates RNO_3 is that they carry four oxygen atoms in a molecule instead of only three and the central atom, chlorine, is also an oxidizer and will combine with hydrogen to form HCl , as opposed to nitrogen in nitrates, which is only carried along as an inert ballast. For alkyl chlorates RCIO_3 the advantage is not so clear. Alkyl chlorates are less stable than alkyl perchlorates, and little is known about alkyl chlorates.

For compounds with the general formula $\text{C}_c\text{H}_h\text{Cl}_{cl}\text{O}_o$, the oxygen balance Ω is defined as

$$\Omega = \left[-32 \left(c + \frac{1}{4}h - \frac{1}{4}cl - \frac{1}{2}o \right) \right] / \text{MW} \times 100\%$$

where c , h , cl , and o represent the number of atoms of each element and MW is the molar mass of the substance. For methyl perchlorate, Ω is +14%, indicating that the

substance has more oxygen in its formula than is needed for complete combustion to CO_2 , H_2O , and HCl . It will rightfully be listed here as an oxidizer.

1 Preparation of Alkyl Perchlorates

Alkyl perchlorates (perchlorate esters, perchloric acid esters) have been prepared by the reaction of alkyl halides with anhydrous silver perchlorate [1], but they are not suitable as rocket propellants. Using a silver salt such as silver perchlorate as one of the reactants automatically makes this a very expensive proposition.

A very useful review of the synthesis and properties of covalent organic perchlorates was compiled and translated in 1988 [2]. The review provided information on the methods of synthesis and reactivities of covalent organic perchlorates and included 141 references. It was preceded by an older review [3].

In one of the first publications on the synthesis of methyl, ethyl, and propyl perchlorates, the pure substances were described as oily liquids and were said to be “extremely explosive” [4]. Surprisingly, the investigators reported a boiling point of 325 K (52°C) for methyl perchlorate and 362 K (89°C) for ethyl perchlorate, suggesting that these compounds were at least thermally stable up to that temperature. Methyl perchlorate can be purified by distillation, boiling point 323 K at 89 kPa (50°C at 670 mm Hg).

Alkyl perchlorates are miscible with ether or ethanol, but they are susceptible to hydrolysis in the presence of water and must be kept dry. Methyl perchlorate hydrolyzed faster than ethyl perchlorate and ethyl perchlorate in turn hydrolyzed faster than propyl perchlorate.

Concern about the hazards of alkyl perchlorate esters was echoed in a study that noted that many physical properties of these compounds are unknown because of their fragility [5].

Primary alkyl iodides reacted with silver perchlorate in pentane, carbon tetrachloride, or 1,1,2-trichlorotrifluoroethane to give primary and secondary perchlorates, with secondary isomers predominating [6, 7]. In benzene, only unrearranged products were obtained. An excess of alkyl iodide and, to a lesser extent, methylene chloride also inhibited isomerization. Isopropyl iodide and allyl iodide, as well as primary iodides, were converted to the corresponding perchlorates and triflates in high yield. Inhibition of rearrangement was rationalized on the basis of the reduced reactivity of complexed silver ions.

Alkyl perchlorates can form by deamination of alkylamines in the presence of perchlorate anion sources [8]. Perchlorate esters form from the interaction of electrophilic halides with alkenes in the presence of excess lithium perchlorate [9].

An easy preparation of secondary alkyl perchlorates that does not require the use of expensive silver perchlorate or alkyl iodides involves the addition of a secondary alcohol or unbranched olefin to a well-stirred emulsion of perchloric acid, sulfuric

acid, and an inert hydrocarbon or fluorocarbon [10]. The acid reagent can be prepared by combining 70% perchloric acid, 96% sulfuric acid, and oleum, or by dissolving lithium perchlorate in 96% sulfuric acid. The formation of isomeric secondary alkyl perchlorates was, in most cases, very rapid and virtually quantitative. The ester products were extracted into the organic layer, from which they may be isolated if desired. The composition of the isomeric mixture is dependent on the reaction conditions and can be made to highly favor one specific desired isomer.

The preparation of tetraperchlorate of methane was attempted [11]. Displacement of halogen from carbon tetrahalides was accomplished starting with either CCl_4 or CBr_4 using the halogen perchlorates ClOClO_3 and BrOClO_3 . Although the displacement process was successful, the generated carbon perchlorate intermediates could not be isolated. Instead, these species decomposed quickly to COCl_2 , CO_2 , and Cl_2O_7 . The perchlorate reactions were often uncontrolled, sometimes explosive, giving CO_2 and Cl_2O_7 . The vigorous displacement reactions that often occurred required moderation by dilution with inert fluorocarbon solvents, but the end result was the same as before. Thus, only COCl_2 , CO_2 , and Cl_2O_7 were found. Tetranitromethane was also examined as a precursor for tetraperchlorate of methane or mixed nitroperchlorate methanes. However, it was unreactive with Cl_2O_4 in the presence or absence of a solvent.

Dichlorine heptoxide is a versatile perchlorylating reagent. Reaction of Cl_2O_7 with alcohols provides a general method of synthesizing alkyl perchlorates, including electronegatively substituted samples, such as 2-fluoro-2,2-dinitroethyl perchlorate and 2,2-dinitropropyl perchlorate, which cannot be prepared by standard methods [12, 13]. Dichlorine heptoxide in carbon tetrachloride is a general reagent for converting alcohols to alkyl perchlorates. Simple primary alcohols, as well as ethylene glycol, 1,4-butanediol, 2,2,2-trifluoroethanol, 2,2-dinitropropanol, 2-fluoro-2,2-dinitroethanol, 2-(2-fluoro-2,2-dinitroethoxy)ethanol, allyl alcohol, and propargyl alcohol, gave the corresponding unrearranged perchlorates. 2-Propanol gave isopropyl perchlorate. 2-Hexanol and 3-hexanol gave mainly unrearranged perchlorates. Ketones gave *gem*-diperchlorates.

The action of chlorine perchlorate on trifluoromethyl iodide at low temperature has resulted in the formation of the simplest perfluoroalkyl perchlorate, F_3COCIO_3 [14]:

Note that in the preceding reaction scheme, iodine was printed as a Roman numeral I in order to avoid confusion with the lowercase L in the symbol for chlorine, Cl. The energy content of alkyl perchlorates can be reduced and the stability improved by making perchlorates of perfluoroalkyl groups instead of hydrogenalkyl groups. Perfluoroalkyl perchlorates can be made by the reaction of chlorine perchlorate with perfluoroalkyl halides or perhalogenated olefins [15]. The reactions of chlorine perchlorate and bromine perchlorate with numerous fluoroalkyl halides were examined. In the case of fluorocarbon iodides, these reactions were generally found to produce high yields of the fluorocarbon perchlorates CF_3ClO_4 , $\text{CF}_3\text{CF}_2\text{ClO}_4$,

$n\text{-C}_7\text{F}_{15}\text{ClO}_4$, $\text{O}_4\text{ClCF}_2\text{CF}_2\text{ClO}_4$, and $\text{ICF}_2\text{CF}_2\text{ClO}_4$. Some insight into the mechanism of formation of these compounds was obtained through the isolation of complex intermediates. Based on their vibrational spectra, these intermediates have an ionic structure. The reactions of Cl_2O_4 or BrClO_4 with perhalogenated olefins produced perhalogenated alkyl perchlorates in high yield.

Oxidative nucleophilic substitution of alkyl iodides with lithium perchlorate, such as the reaction of alkyl iodides and lithium perchlorate, proceeding in the presence of nitronium tetrafluoroborate as an oxidant, can be used to synthesize alkyl perchlorates, including those containing an adamantyl nucleus [16]. The spectral properties of alkyl perchlorates were then studied in detail for the first time.

2 Physical Properties of Alkyl Perchlorates

The physical properties of some of the higher alkyl perchlorates are listed in Table 1.

Table 1: Physical properties of alkyl perchlorates.

Compound	Formula	Boiling point (°C) at reduced pressure	Index of refraction, n_D^{25}	Density at 25 °C
<i>n</i> -Pentyl perchlorate	$\text{C}_5\text{H}_{11}\text{ClO}_4$	51.5/11 mm Hg	1.4042	—
<i>n</i> -Hexyl perchlorate	$\text{C}_6\text{H}_{13}\text{ClO}_4$	52/4.5 mm Hg	1.4146	1.11 g/cm ³
<i>n</i> -Heptyl perchlorate	$\text{C}_7\text{H}_{15}\text{ClO}_4$	49–51/2.4 mm Hg	1.5170	—
<i>n</i> -Octyl perchlorate	$\text{C}_8\text{H}_{17}\text{ClO}_4$	55–60/1.5 mm Hg	1.4192	1.07 g/cm ³

Data source: [17]

2.1 Molecular Structure of Alkyl Perchlorates

The molecular structure of methyl perchlorate is illustrated in Figure 1. Methyl perchlorate as a monopropellant or oxidizer may be compared to methyl nitrate, except that it contains more oxygen and the central halogen atom contributes to the oxygen balance, whereas nitrogen does not.

Figure 1: Molecular structure of methyl perchlorate.

Table 2: Predicted enthalpies of formation and decomposition of methyl perchlorate.

Method	ΔH_f , kJ/mol	ΔH_f , kJ/kg	ΔH_{dec} , kJ/mol	ΔH_{dec} , kJ/kg
G2	33.23	290.2	-804.9	-7030
G3	25.61	223.7	-797.3	-6964

Data source: [18]

The molecular properties, including enthalpies of formation and decomposition, of methyl chlorate and methyl perchlorate were predicted by a high-level computational study of the structure, vibrational frequencies, and enthalpies of reaction of methyl perchlorate were calculated [18]. Of interest was the amount of energy given off per unit mass when these compounds decomposed, as the specific enthalpy of decomposition is one useful measure of the utility of a high-energy material. All calculations used the G2 and G3 methods of Gaussian 03 computational chemistry software package, and the results are listed in Table 2.

Mixtures of perchloric acid with organic fuels are most likely detonable, but some people want to use them as rocket propellants [19].

3 Chemical Properties of Alkyl Perchlorates

3.1 Reactions of Alkyl Perchlorates

Alkyl perchlorates may serve as alkylating agents and are sometimes only formed as intermediates in alkylation reactions with alkanols and perchloric acid. Alkyl perchlorates that are formed as intermediates may undergo subsequent fission to carbonium and perchlorate ions [5].

Methyl perchlorate is a good methylating agent, more powerful than methyl sulfate. Much of the work on methyl perchlorate has focused on its hydrolysis or solvolysis. Methyl perchlorate solvolysis kinetics was studied in methanol, ethanol, isopropanol, *tert*-butanol, and 80% aqueous ethanol [20]. Methyl perchlorate for this study was prepared as a solution in benzene by the reaction of methyl iodide with silver perchlorate and the removal of precipitated silver iodide by filtration.

The kinetics of reactions of methyl perchlorate in hydroxylic solvents have been studied extensively [21, 22]. Such reactions may be used for the safe disposal of excess alkyl perchlorates.

3.1.1 Thermal Decomposition of Alkyl Perchlorates

All alkyl perchlorates are potentially explosive, and they are unlikely to be used as rocket propellants. The *n*-amyl perchlorate was the least stable in a group of five per-

chlorates tested. It has been possible to stabilize them by forming inclusion compounds (clathrates, endocytos) with urea, forming stable crystals analyzed by XRD [17]. The ease of formation of the urea inclusion compound was proportional to the chain length of the alkyl perchlorate. The resulting crystalline complexes had no apparent shock sensitivity in small quantities [23].

Difluoroamino Compounds

Many organic energetic materials do not fit in the oxidizer category because they are underoxidized. Other energetic materials are not suitable as monopropellants because they are solids. These organic solid materials are discussed in another volume on solid propellant additives. Solid propellant additives can be energetic materials, or they can be nitrogen-rich additives, which are often added as coolants to solid gas generants.

Alkyl perchlorates and alkyl difluoroamino compounds have been considered as rocket propellants, but their notorious shock sensitivity prevented further development. Other energetic additives, many of those used as energetic plasticizers, do not contain oxygen, nitro, or nitrate groups at all; they contain difluoroamino —NF_2 groups instead.

When reacting with strongly reducing light alkali or earth alkaline metals, even such inert organic fluorine compounds as tetrafluoromethane or polytetrafluoroethylene can act as oxidizers. This exothermic reaction is widely used for pyrotechnic mixtures for igniters and flares.

In addition to compounds with merely relatively stable C—F bonds, other organic compounds in which the fluorine is bound to carbon via nitrogen or oxygen atoms are very energetic, often to a point where they are so sensitive that they are difficult to handle safely.

Organic nitro compounds with the —NO_2 group are known to be energetic materials. Replacing the two oxygens attached to nitrogen by two fluorine atoms, forming —NF_2 groups, leads to the formation of equally energetic or even more energetic materials. Studies have been conducted comparing the enthalpies of formation and detonation performance of polynitro compounds with those of polydifluoroamino compounds, for instance by progressively replacing one or more nitro groups in a molecule with difluoroamino groups [1, 2]. There may be some overlap in the information provided in this book on difluoroamino compounds and nitro compounds, in particular in areas where the properties of these two groups of energetic materials are compared. A complete evaluation of those mixed substituent energetic compounds is possible only by reading both sections.

Fluorine, even in the form of difluoroamino groups and diluted by the presence of nitrogen, is a very powerful oxidizer. Organic difluoroamino compounds, also called NF compounds or “domino” compounds, have a higher specific impulse than their corresponding nitro group analogs where the nitrogen carries two oxygen atoms instead of two fluorine atoms. This is partially because the exhaust products of RNF_2 combustion have a lower molecular mass than those from nitro compounds.

The simplest difluoroamino compound is difluoroamine, F_2NH , which was described in *Encyclopedia of Oxidizers*, in the chapter “Nitrogen Fluorides,” and can be used to introduce the —NF_2 group into other compounds.

Some energetic solid additives containing difluoroamino groups were intended as replacements for 1,3,5-trinitro-1,3,5-triazacyclohexane (RDX), 1,3,5,7-tetranitro-1,3,5,7-tetraazacyclooctane (HMX), or other nitramines, in the hope of achieving higher performance, better thermal stability, lower sensitivity, and higher density. Not all solid difluoroamino compounds meet these criteria. Other applications of liquid difluoroamino compounds are as monopropellants (see *Encyclopedia of Monopropellants*) and as energetic plasticizers (low-volatility liquids) or energetic binders in solid propellants. Additional information on applications of these NF compounds can be found in those sections. This section deals mostly with liquid difluoroamino compounds and provides information on some of the more general aspects of difluoroamino compounds that are of equal interest to all previously mentioned applications.

As far as the nomenclature is concerned, different spellings are in use: We use the word *difluoroamino* compounds, but the terms *difluoramino* or *difluoramine* can also occasionally be found in the literature. The position of the two fluorine atoms on the same nitrogen atoms is sometimes described as *geminal difluoroamino* compounds or *N,N-difluoroamino* compounds. In the propellant chemistry jargon these compounds are also called *domino compounds*.

Just as a reminder, the name difluoroamino is often abbreviated as difluoramino, omitting the “o.” At other times, the compounds are called difluoroamine instead of difluoroamino compounds. *N,N*-difluoromethylamine is also called *N,N*-difluoromethanamine.

1 Summary Literature on Organic Fluoroamino Compounds

Several summary publications on NF compounds may serve as an introduction to this heavily researched, but now mostly forgotten, chemistry; what is lacking is a systematic summary of these compounds with all physical, chemical, and safety properties in one place. Much of the literature on —NF_2 compounds had been classified at one time, but eventually it was declassified at various times and remained burdened with other distribution limitations. Considering how much money has been spent on developing —NF_2 compounds over the past 50 years, it seems that the interest in these compounds dropped abruptly, and it is a shame that nobody has since taken the time to write a complete historical summary of what was done. Dozens, perhaps hundreds, of research reports continue to collect dust on some agency's bookshelves and may never penetrate to the scientific community. The summary of the literature in this chapter of the book at hand is incomplete and would require a substantial amount of work to bring it to a state of completeness. The more simple —NF_2 compounds are often overlooked, and some publications delve immediately into the more complex —NF_2 compounds.

Many of the —NF_2 compounds listed in some of the review publications are very complex and would be difficult to prepare for actual use. Some have only been pre-

pared in milligram quantities, in part because of the hazards involved in their synthesis.

Three literature reviews summarized the chemistry revealed during the period 1955–1967 directed toward the development of energetic oxidizers for use in advanced chemical rocket propellants [3]. The source material for these reviews included over 1200 technical reports and 1150 references. An extensive chapter on organic CNF oxidizers described simple NF_2 -substituted hydrocarbons and halocarbons, NF compounds containing oxygen functional groups, and NF compounds containing N–N bonds.

A later review of organic difluoroamine derivatives published as a chapter of a book on high-energy-density materials (HEDMs) was very specific only to cyclic difluoroamino nitramines, especially *gem*-bis(difluoroamino)-substituted analogs of conventional cyclic nitramines [4].

2 Monofluoroamino Compounds

Monofluoroamino compounds are of little interest as rocket propellants compared to difluoroamino compounds. They are used as selective electrophilic fluorinating reagents in organic synthesis. Dialkyl monofluoroamino compounds of the type R_2NF are more energetic than the secondary amines from which they are derived by replacing a hydrogen on the linking nitrogen $-\text{NH}-$ group of a secondary amine with a fluorine atom. Examples include methyl *N*-fluoroamine, H_3CNHF , trifluoromethyl *N*-fluoroamine, F_3CNHF , and dimethyl *N*-fluoroamine, $(\text{H}_3\text{C})_2\text{NF}$.

Dialkyl monofluoroamino compounds can carry explosophoric groups in the alkyl groups that further enhance the energetic properties of the molecule. For instance, the kinetics of thermal decomposition of bis(2,2-dinitropropyl)-*N*-fluoroamine were studied in the liquid phase [5]. The reaction was autocatalytic in the melt. In dilute solution, the reaction rate was described by a first-order law.

Other types of monofluoro-nitrogen compounds are the fluoroimines, which carry a $>\text{C}=\text{NF}$ group instead of a $\text{C}-\text{NF}_2$ group [6]. They contain less oxidizer and are of no interest as rocket propellants.

Similar compounds are known that carry a nitro group on the nitrogen and, thus, belong in the category of nitramines. Other energetic compounds carry a fluorine atom as well as a nitro group on the same nitrogen atom from an alkylamine. The enthalpies of formation of three *N*-fluoronitramines were listed in [7], but very little is known about these compounds.

3 Difluoroamino Compounds

The following sections describing the properties of —NF_2 compounds are arranged first in sequence by the number of carbon atoms in the organic skeleton and after that by the number of difluoroamino groups in the molecule. Compounds that carry additional substituents (nitro groups, nitrile groups, hydroxyl groups, amino groups, cyano groups) on the carbon skeleton are listed last. The following introductory summary concentrates on difluoroamino alkanes without additional substituents on the alkyl rest. A few compounds with multiple substitution are listed in what follows as examples, but the listing is far from complete. Also, we have neglected most R—NF_2 compounds where the R group is an unsaturated alkylene group.

It is common practice to abbreviate names of difluoroamino compounds and use acronyms. This has resulted in an alphabet soup of acronyms, and occasional confusion and mix-ups were unavoidable, in particular if the same abbreviation was used for two different compounds. Some of the acronyms originated as code names during a period when the mere existence of these compounds was classified as confidential information for national security reasons and their intended use as propellants or explosives was kept secret. Some of the common abbreviations are summarized in Table 1, arranged by increasing number of carbon atoms.

Table 1: Acronyms and code names used for difluoroamino compounds.

Acronym	Formula	Gross formula	Name
Compound H	$\text{F}_2\text{C}(\text{NF}_2)_2$	$\text{C}_1\text{F}_6\text{N}_2$	bis(difluoroamino)difluoromethane
Compound R	$\text{FC}(\text{NF}_2)_3$	$\text{C}_1\text{F}_7\text{N}_3$	tris(difluoroamino)fluoromethane
Compound T or Compound Delta	$\text{C}(\text{NF}_2)_4$	$\text{C}_1\text{F}_8\text{N}_4$	tetrakis(difluoroamino)methane
DDP	$\text{H}_3\text{C—C}(\text{NF}_2)_2\text{—CN}$	$\text{C}_3\text{H}_3\text{F}_4\text{N}_3$	2,2-bis(difluoroamino)propionitrile
1,2,2-TP	$\text{H}_3\text{C—C}(\text{NF}_2)_2\text{—CH}_2\text{—NF}_2$	$\text{C}_3\text{H}_4\text{F}_6\text{N}_3$	1,2,2-tris(difluoroamino)propane
1,1-DP	$\text{H}_3\text{C—CH}_2\text{—CH}(\text{NF}_2)_2$	$\text{C}_3\text{H}_6\text{F}_4\text{N}_2$	1,1-bis(difluoroamino)propane
1,2-DP	$\text{H}_3\text{C—CH}(\text{NF}_2)\text{—CH}_2\text{—NF}_2$	$\text{C}_3\text{H}_6\text{F}_4\text{N}_2$	1,2-bis(difluoroamino)propane
1,3-DP	$\text{F}_2\text{N—CH}_2\text{—CH}_2\text{—CH}_2\text{—NF}_2$	$\text{C}_3\text{H}_6\text{F}_4\text{N}_2$	1,3-bis(difluoroamino)propane
2,2-DP	$\text{H}_3\text{CC}(\text{NF}_2)_2\text{CH}_3$	$\text{C}_3\text{H}_6\text{F}_4\text{N}_2$	2,2-bis(difluoroamino)propane
DIN	$\text{H}_3\text{C—C}(\text{CH}_3)(\text{NF}_2)\text{—CN}$	$\text{C}_4\text{H}_6\text{F}_2\text{N}_2$	2-difluoroamino-2-methylpropionitrile
2,3-DB-1	$\text{H}_3\text{C—CH}(\text{NF}_2)\text{—CH}(\text{NF}_2)\text{—CH}_3$	$\text{C}_4\text{H}_8\text{F}_4\text{N}_2$	2,3-bis(difluoroamino)butane
IBA	$(\text{H}_3\text{C})_2\text{C}(\text{NF}_2)\text{—CH}_2\text{—NF}_2$	$\text{C}_4\text{H}_8\text{F}_4\text{N}_2$	1,2-bis(difluoroamino)-2-methylpropane
TBD	$(\text{H}_3\text{C})_3\text{CNF}_2$	$\text{C}_4\text{H}_9\text{F}_2\text{N}$	<i>tert</i> -butyldifluoroamine
1-DB	$\text{H}_3\text{CCH}_2\text{CH}_2\text{CH}_2\text{NF}_2$	$\text{C}_4\text{H}_9\text{F}_2\text{N}$	1-difluoroaminobutane
2-DB	$\text{H}_3\text{CCH}_2\text{CH}(\text{NF}_2)\text{CH}_3$	$\text{C}_4\text{H}_9\text{F}_2\text{N}$	2-difluoroaminobutane
TMEA	$(\text{H}_3\text{C})_2\text{C}(\text{NF}_2)\text{—CH}(\text{NF}_2)\text{—CH}_3$	$\text{C}_5\text{H}_{10}\text{F}_4\text{N}_2$	2,3-bis(difluoroamino)-2-methylbutane

3.1 History of Difluoroamino Compounds

Although an organic difluoroamine derivative (CF_3NF_2 byproduct formed by direct fluorination of silver cyanide) had been reported as early as 1936, the impetus for the major development of this class of compound was the recognition by the US Advanced Research Projects Agency and Department of Defense that various N–F compounds, especially organic difluoramines, might be superior rocket propellant oxidizers [8]. Among others, Project Principia was carried out over the period 1958–1965 to explore the possibilities offered by these materials. While research projects funded by this program ended in 1969, open-literature publications of their results appeared for several years afterward. Hundreds of organic difluoramines, including hundreds with the *gem*-bis(difluoroamino) linkage, $>\text{C}(\text{NF}_2)_2$, were prepared under the aegis of Project Principia and similar efforts abroad. Generally the idea was that the higher the number of difluoroamino groups per molecule, the more energetic the material would become. The $-\text{NF}_2$ groups acted much like nitro ($-\text{NO}_2$) groups do in explosives such as trinitrotoluene (TNT), and even more so. However, because the difluoroamino group has a higher density than the nitro group, the compounds had the prospect of being superior propellant oxidizers or binders in solid propellant formulations or explosives. Project Principia failed to produce difluoroamino-based rocket propellant oxidizer candidates sufficiently superior to actually replace previously used nitro compounds. Almost all difluoroamino derivatives at that time possessed inadequate stability, insensitivity, or physical properties to serve as viable replacements. Organic difluoroamine research languished for a couple of decades afterward, though results continued to be published throughout the 1970s and 1980s by a few researchers. It is unfortunate that following the abandonment of difluoroamino compound development nobody took the time to summarize all the good work that had been done. That task would be very complicated because much of the information had never been published in scientific journals and much of it is scattered throughout the patent literature. Only a few publications describe the properties of the pure ingredients by themselves. Instead, an order of magnitude more patent publications attempt to lay claim to new rocket propellants containing $-\text{NF}_2$ compounds. The main prevailing benefit of the development of difluoroamino compounds appears to be in energetic plasticizers.

For the chemistry history buff, it is interesting to note that perfluoroguanidine (PFG) and $-\text{NF}_2$ compounds played a role in a Cold War spy story when a spy in one of the hostile governments gathering intelligence on the other's progress in developing new rocket propellants was caught in the act [9].

Later work was aimed at heterocyclic analogs to RDX or HMX where some or all of the $>\text{N}-\text{NO}_2$ groups were replaced by *gem*-bis(difluoroamino) $>\text{C}(\text{NF}_2)_2$ groups.

3.2 Preparation of Difluoroamino Compounds

The synthesis and chemical reactions of organic difluoroamines and the relationships between molecular structure and explosive sensitivity were evaluated in a series of research reports [10, 11]. These reports contain useful property data (melting point [m.p.], boiling point [b.p.], index of refraction) for almost a hundred difluoroamino compounds, mostly with carbon chains in the C₆–C₈ range and with cyclohexane.

N,N-difluoromethylamine is also called methyldifluoroamine or *N,N*-difluoromethanamine. Preparing NF compounds by direct N-fluorination of amides like urea or guanidine in aqueous solution often resulted in fluorinative cleavage, but ethyl N-fluorocarbamate was obtained from ethyl carbamate.

Direct fluorination with fluorine gas, converting a –NH₂ group into a –NF₂ group, is possible in the case of aminoperfluorophenyl compounds, where the benzene ring carried one amino group and none or one other substituent (–CF₃, NO₂, –CN) but had to work in dilution and with lots of precautions [12].

The electrooxidation of NF₂H in acidic solutions results in the formation of N₂F₄ by recombination of [•]NF₂ radicals in the absence of other radical formers. In the presence of alkyl radicals, RNF₂ compounds are formed instead by radical recombination [13].

Alkyl difluoroamines can be prepared by aqueous fluorination of N-substituted alkyl sulfonamides and alkyl sulfamates [14, 15]. For example, the fluorination of sodium *N*-methylsulfamate gave methyldifluoroamine, m.p. 158 K = –115 °C, b.p. 257 K = –16 °C. The same method can be used to prepare other RNF₂ compounds, for example: EtNF₂, b.p. 288 K = 15 °C; *n*-PrNF₂, b.p. 338–340 K = 65–67 °C; *iso*-PrNF₂, b.p. 317–319 K = 44–46 °C, *n*-BuNF₂, b.p. 354–357 K = 81–84 °C; *iso*-BuNF₂, b.p. 334 K = 61 °C; *sec*-BuNF₂, b.p. 359 K = 86 °C; and *n*-pentylNF₂, b.p. 375–376 K = 102–103 °C.

3.2.1 Preparation of Geminal Bis(difluoroamino) Compounds

Geminal bis(difluoroamino) compounds were prepared by the reaction of difluoroamine, F₂NH, in the presence of a strong dehydrating acid, which does not oxidize the F₂NH, at 263–308 K (–10 to +35 °C) with aldehydes or ketones [16–18]. The first example of this reaction was the synthesis of 2,2-bis(difluoroamino)propane (DP) from acetone and difluoroamine in sulfuric acid. Yields of 2,2-DP were generally in the neighborhood of 75%, although in one reaction even a 95% yield was obtained. The example compounds listed in Table 2 were prepared.

Geminal bis(difluoroamino) derivatives of the type (F₂N)₂CR₂ can be produced by the reaction of HNF₂ with F₂NCR₂⁺ carbonium ions through the slow addition of a protonating agent (e.g., concentrated H₂SO₄ or a low concentration of oleum) to a mixture of a carbonyl compound and HNF₂ (in 1:2 or greater proportion) formed by condensing the reactants at 195 K (–78 °C) in a solvent, warming to 263 K (–10 °C), and separating the two layers in suitable solvents (CHCl₃ or CH₂Cl₂) [19]. The geminal bis(difluoroamino) compounds listed in Table 3 were prepared in this way.

Table 2: Properties of geminal bis(difluoroamino) compounds.

Compound name	Boiling point		At reduced pressure mm Hg	Melting point	
	K	°C		K	°C
2,2-bis(difluoroamino)propane	346	73	760		
1,1-bis(difluoroamino)cyclopentane ^a	308–309	35–36	20		
3,3-bis(difluoroamino)pentane	313–314	40–41	30		
1,1-bis(difluoroamino)cyclohexane	317	44	7		
1,1,4,4-tetrakis(difluoroamino)cyclohexane	—	—	—	376	103 ^b
1,1-bis(difluoroamino)propane	298	25	260		
3-methyl-2,2-bis(difluoroamino)pentane	332	59	27		
2,2,5,5-tetrakis(difluoroamino)hexane	343	70	4		
2,2,7,7-tetrakis(difluoroamino)octane	344–345	71–72	0.1	333	60

^aHas a refractive index of $n_D^{25} = 1.3887$ ^bPhase change at 353 K (80 °C)

See also [20, 21].

gem-Bis(difluoroamino) cycloalkanes can be prepared via direct fluorination of geminal bisacetamides [22]:

5,5-bis(difluoroamino)hexahydro-1,3-dinitropyrimidine, RNFX,

is an RDX analog, and HNFX, 3,3,7,7-tetrakis(difluoroamino)octahydro-1,5-dinitro-1,5-diazocine, is an HMX analog, expected to have similar or even better explosive properties [23, 24]. The acronym HNFX signifies the HMX analog of the class of NF_2 -modified cyclic nitramine explosives.

3.2.2 Preparation of Vicinal Bis(difluoroamino) Compounds

Vicinal bis(difluoroamino) compounds can be prepared by the addition of N_2F_4 to alkenes [25, 26]. This method is easier than the preparation of geminal bis(difluoroamino) compounds, which depend on the availability of difluoroamine, which is not commercially available.

3.2.3 Preparation of C_1 Difluoroamino Compounds

One of the oldest methods for the preparation of *N,N*-difluoromethylamine and *N,N*-difluoroethylamine involved the photochemical reaction of CH_3I or $\text{C}_2\text{H}_5\text{I}$ with N_2F_4 when subjected to ultraviolet excitation ($>2750 \text{ \AA}$) [27].

A photochemical process and a low-temperature fluorination procedure were used to prepare CF_3NF_2 . The latter was the better method. CF_3NF_2 can be prepared by a photochemical process, i.e.,

The photochemical method yielded many side products that required distillation and vapor phase chromatography to remove. A better method involved low-temperature

direct fluorination of KSCN in the presence of KF as a catalyst

The initial attempt at this reaction produced a quantitative yield of gaseous products consisting of CF_3NF_2 and SF_6 , which could be separated completely by two distillations.

Bis(difluoroamino)difluoromethane can be prepared by the direct fluorination of cyanuric chloride or aminoiminomethane sulfinic acid [28]. The direct fluorination of guanylurea sulfate at 263 K (-10°C) gives a mixture of several RNF_2 compounds, which is difficult to separate, and the yields are very poor. The products include bis(difluoroamino)difluoromethane, tris(difluoroamino)fluoromethane, pentafluoroguanidine, tetrafluoroformamidine, and a few others [29].

When ammonium fluoride NH_4F and formaldehyde (37% CH_2O) in aqueous solution were treated with a gaseous fluorine/nitrogen mixture at 273–275 K (0 – 2°C) for 1 h and the exit gases were condensed in two cold traps cooled to 133 K (-140°C), the condensate was mostly $\text{CH}_2(\text{NF}_2)_2$, with minor amounts of FCH_2NF_2 , CH_2F_2 , CHF_3 , and NF_3 .

Fluorine gas was passed through a glass U-tube containing potassium cyanide at room temperature, the off-gas was passed through a cold trap at liquid nitrogen temperature, and the condensate was purified by preparative gas chromatography (GC) and yielded difluoroaminotrifluoromethane, F_3CNF_2 , in 41% yield based on the amount of fluorine used [30]. The experiment was repeated at 253 K (-20°C) with similar results.

In many cases the fluorination reactions of organics result in mixtures of compounds with different degrees of fluorination. Bis(difluoroamino)difluoromethane and tris(difluoroamino)fluoromethane can be separated by selective adsorption onto crystalline zeolites as adsorbing materials [31]. A Linde 5A mol sieve will selectively adsorb bis(difluoroamino)difluoromethane while excluding the slightly larger tris(difluoroamino)fluoromethane molecule.

The polymeric reaction product of guanidine $(\text{H}_2\text{N})_2\text{C}=\text{NH}$ and urethane EtOCONH_2 in a stainless-steel boat was placed in a nickel tube, the tube was flushed with nitrogen, and a gas mixture of 8.9% fluorine in nitrogen was passed through for 3.66 h to give a yellow amorphous solid and a volatile fraction, which was condensed in a cold trap and after fractionation was found to contain $(\text{F}_2\text{N})_3\text{CF}$, b.p. = 278 K = 5°C , and density at 198 K = -75°C = $\sim 1.9\text{ g/cm}^3$, and the heat of evaporation was $\Delta H_{\text{vap}} = \sim 27\text{ kJ/mol} = \sim 6.5\text{ kcal/mol}$ [32]. The condensate also contained $(\text{F}_2\text{N})_2\text{CF}_2$ and traces of $(\text{CF}_3)_2\text{NF}$, CF_3NF_2 , and SiF_4 . The properties of $(\text{F}_2\text{N})_2\text{CF}_2$ were measured and reported as follows: b.p. = 241 K = -32°C , density at 298 K = 25°C = 1.901 g/cm^3 (under pressure), and heat of evaporation $\Delta H_{\text{vap}} = \sim 22\text{ kJ/mol} = \sim 5.3\text{ kcal/mol}$. Similarly $\text{F}_2\text{NCF}=\text{NF}$, $(\text{F}_2\text{N})_2\text{C}=\text{NF}$, $\text{F}_2\text{NCF}_2\text{NFCF}(\text{NF}_2)\text{NFCF}(\text{NF}_2)_2$, $\text{F}_2\text{NCF}_2\text{NFCF}_2\text{NFCF}(\text{NF}_2)_2$, and $\text{CF}_3\text{NFCF}(\text{NF}_2)_2$ were prepared.

The fluorination of aqueous solutions of urea was found to be a more readily controllable reaction to produce *N,N*-difluorourea, which is a useful intermediate in the production of other RNF_2 compounds [33]. The moderating effect of the solvent allowed the use of two mols of fluorine per mol of urea, and a 74% yield of *N,N*-difluorourea was isolated by ether extraction. *N,N*-Difluorourea was also prepared by the fluorination of a suspension of urea in acetonitrile. *N,N*-Difluorourea is a white solid, m.p. 314 K (41–41.5 °C), which was isolated in two crystalline forms, platelets by sublimation and needles by crystallization from halogenated solvents. *N,N*-Difluorourea must be handled with caution because it is a sensitive explosive. The amino group of *N,N*-difluorourea is unreactive, and further fluorination did not yield more highly fluorinated ureas.

PFG is a very useful reagent for the preparation of other difluoroamino compounds, including tris(difluoroamino)methane [34].

Fluorination of azidotrifluoromethane with added KF as a catalyst resulted in the formation of difluoroamino trifluoromethane in a direct, reproducible, and high-yield reaction [35]. The optimum rate of conversion with minimum degradation was obtained at 343–353 K (70–80 °C). The fluorination of CF_3N_3 to CF_3NF_2 can be catalyzed by KF [36].

Tetrakis(difluoroamino)methane can be synthesized by two different processes: One, developed by the Minnesota Mining and Manufacturing Company, involved the reaction of ammonia and PFG followed by the direct fluorination of the adduct. The other process, developed by the American Cyanamid Company, was similar and involved the reaction of isocyanic acid (HNCO) and PFG to form an adduct, followed by direct fluorination to Compound Delta.

Highly fluorinated fluoroaminomethane products, e.g., $\text{C}(\text{NF}_2)_4$, are useful as rocket fuels. Compounds such as difluoroamino(fluoroamino) fluoromethyl isocyanate, tris(difluoroamino)fluoromethane, bis(difluoroamino)fluoroaminomethyl isocyanate, tris(difluoroamino)methyl isocyanate, and tetrakis(difluoroamino)methane were synthesized [37]. For instance, biguanide was mixed with NaF, placed in a fluid-bed reactor, and fluidized and fluorinated by passing a carrier gas (4% F and 96% He) at a temperature of 343 K (70 °C) for 4 h. The product was collected and purified, containing 27% perfluoroformamidine, 18% PFG, and 8% difluorocyanamide. Difluorocyanamide $\text{F}_2\text{NC}\equiv\text{N}$ is a useful fluorinating agent.

Difluoroaminoazidomethane derivatives can be prepared by the reaction of fluoroguanidine compounds $\text{R}_2\text{C}=\text{NF}$ ($\text{R} = \text{F}, \text{NF}_2, \text{N}_3$) with hydrazoic acid and difluorine in inert halogenated solvents [38]. Compounds prepared by this method included $(\text{F}_2\text{N})_2\text{C}(\text{N}_3)\text{NHF}$, $(\text{F}_2\text{N})_3\text{CN}_3$, and $(\text{F}_2\text{N})_2\text{CFN}_3$.

In addition to difluoroamino compounds with $\text{C}-\text{NF}_2$ linkages, compounds have been prepared where the alkyl group and the $-\text{NF}_2$ group are linked by an oxygen $-\text{O}-$ bridge. Examples are H_3CONF_2 and F_3CONF_2 [39].

3.2.4 Preparation of Linear Difluoroamino Compounds

3.2.4.1 Preparation of C₂ Difluoroamino Compounds

Fluorination of 13.2 g (0.15 mol) of ethylurea in 350 mL of water (0–5 °C, 0.35 mol of fluorine, 2 h) gave 6 g (49% yield) of difluoroaminoethane identified by its infrared (IR) spectrum, which was condensed from the exit gas in a 195 K (–78 °C) trap [33].

1,2-Bis(difluoroamino)ethylnitramine $\text{F}_2\text{N}-\text{CH}_2-\text{CH}(\text{NF}_2)\text{NHNO}_2$ can be prepared by the nitration of 1,2-bis(difluoroamino)ethyl isocyanate with a 50/50 mixture of HNO_3 and H_2SO_4 [40]. The nitrated mixture must be neutralized with urea before the product can be isolated. The urea salt that formed was filtered off, the CH_2Cl_2 solution was dried with MgSO_4 and filtered, and the CH_2Cl_2 was removed under vacuum. The residue was maintained under high vacuum overnight and then distilled to give a colorless liquid, with a b.p. of 325 K (52 °C) at 0.25 mm Hg. The liquid was identified as 1,2-bis(difluoroamino)ethylnitramine by IR spectroscopy, nuclear magnetic resonance (NMR) spectroscopy, and mass spectrometry (MS).

The dry reaction of a sodium cyanamide/ MgF_2 mixture with diluted F_2/N_2 gas yielded (difluoroaminodifluoromethyl)fluorocyanamide $\text{NF}_2\text{CF}_2\text{NFCN}$, a volatile compound that could be condensed in a cold trap at 195 K [41]. The liquid boils at 291 K (18 °C). This can be dissolved in N_2O_4 and used as oxidizer for N_2H_4 .

3.2.4.2 Preparation of C₃ Difluoroamino Compounds

Fluorination of 102 g (1.0 mol) *n*-propylurea in 700 mL water (1.5 mol of fluorine, 6 h, 0–5 °C) gave 15 g (0.16 mol) 1-difluoroaminopropane, b.p. 318 K (45 °C), which was condensed from the exit gas in a 195 K (–78 °C) trap [33]. In a similar way, a solution of 70 g (0.70 mol) tetrahydro-2-pyrimidone in 650 mL water was allowed to react with fluorine at 0–5 °C for 1.5 h, giving a 6% yield of 80% pure (GC analysis) 1,3-DP after fractionated distillation, b.p. 38–50 °C (25 mm Hg).

A mixture of allyldifluoroamine, 1,2,3-tris(difluoroamino)propane, 1,2,3-tribromopropane, and 1,2-dibromo-3-(difluoroamino)-propane was obtained by treating allyl bromide with N_2F_4 at 503 K (230 °C) [42, 43]. Instead of performing this reaction in a single step and ending up with a lot of byproducts, a more selective product mix is achieved by performing the reaction in two steps [44]. In the first step, equal amounts of allyldifluoroamine and 1,2,3-tris(difluoroamino)propane were formed. Allyldifluoroamine was separated by distillation and treated for 12 h with N_2F_4 at 448 K (175 °C) and 103 kPa (15 psia) to give the desired 1,2,3-tris(difluoroamino)propane in essentially quantitative yield. 1,2,3-Tris(difluoroamino)propane had a b.p. of 400 K (127 °C) and a freezing point of 162 K (–111 °C). It could be mixed with tetranitromethane (TNM), boron powder, and a binder to give a rocket propellant with a specific impulse of 282 s.

2,3-Bis(difluoroamino)-1-propanol can be prepared by the reaction of allyl trifluoroacetate with tetrafluorohydrazine, making 2,3-bis(difluoroamino)propyl trifluoroacetate, followed by transesterification with an excess of methanol, giving 2,3-bis(difluoroamino)-1-propanol with a b.p. of 317 K at 400 Pa (44 °C at 3 mm Hg) [45].

gem-Difluoroamino compounds can be prepared by treating carbonyl compounds with F_2NH in the presence of a strong dehydrating acid that does not oxidize the F_2NH , at 263–308 K (–10 to +35 °C) [17, 46]. The reaction of acetone with F_2NH in concentrated H_2SO_4 gave 2,2-DP with a b.p. of 346 K (73 °C) at ambient pressure or 298 K at reduced pressure of 35 kPa (25 °C at 260 mm Hg).

When the amino group in allylamine is protected by being fully protonated by a strong acid such as perchloric acid, forming the allylammonium perchlorate, $H_2C=CHCH_2NH_3ClO_4$, the reaction with N_2F_4 leaves the amino group intact and instead N_2F_4 adds only to the double bond in a typical difluoroamination reaction forming the 2,3-bis(difluoroamino)propaneammonium perchlorate $F_2NCH_2CH(NF_2)CH_2NH_3ClO_4$, with a m.p. of 371–373 K (98–100 °C), and an impact sensitivity of 25 kg·cm [47]. Similarly, the energetic salt 2,3-bis(difluoroamino)propylhydrazinium(2+) perchlorate $F_2NCH_2CH(NF_2)CH_2NHNH_2 \cdot 2HClO_4$ was prepared.

3.2.4.3 Preparation of C_4 Difluoroamino Compounds

tert-Butyl difluoroamine can be prepared by dissociation of tetrafluorohydrazine into $\cdot NF_2$ free radicals and combining them with *tert*-butyl radicals via the decomposition of azoisobutane in the presence of N_2F_4 or by illumination of *tert*-butyl iodide vapor with N_2F_4 [11].

The reaction of N_2F_4 with butadiene results in the addition of only two $-NF_2$ groups in the terminal positions, forming 1,4-bis(difluoroamino)-butene-2,3, which on subsequent reaction with N_2O_5 gives 1,4-bis(difluoroamino)-2,3-bis(nitrato)butane, $F_2NCH_2CH(ONO_2)CH(ONO_2)CH_2NF_2$, a very energetic compound with a density of 1.7 g/cm³, a b.p. of 335–341 K at 13 Pa (62–68 °C at 0.1 mm Hg), and an autoignition temperature of 468 K (195 °C) [48].

A series of seven difluoroamino compounds (five aliphatic, one aromatic, and one heterocyclic) were prepared by F_2NH substitution reactions, including $F_2NCH_2N(NO_2)(CH_2)_2N(NO_2)CH_2NF_2$, $F_2NCH_2N(NO_2)CH_2N(NO_2)CH_2NF_2$, $F_2NCH_2N(NO_2)CH_2NH_2$, *p*-MeC₆H₄SO₂N(CH₂NF₂)₂, AcN(CH₂NF₂)₂, $F_2NCH_2NEtCHO$, and a piperazine derivative [49]. These compounds are potentially useful as energetic additives in solid rocket propellants.

Treatment of $(O_2N)_3CCH_2N(NO_2)CH_2CH_2OH$, $(O_2N)_3CCH_2N(NO_2)CH(CH_2OH)_2$, $(O_3N)_3CCH_2N(NO_2)C(CH_2OH)_3$, or $O_2NN[CH_2C(NO_2)CH_2OH]_2$ with $FN=C(NF_2)_2$ in MeCN in the presence of urea, followed by fluorination, gave $(O_2N)_3CCH_2N(NO_2)=CH_2CH_2OC(NF_2)_3$, $(O_2N)_3CCH_2N(NO_2)CH[CH_2OC(NF_2)_3]_2$, $(O_2N)_3CCH_2N(NO_2)C[CH_2OC(NF_2)_3]_3$, and $O_2NN[CH_2C(NO_2)_2CH_2OC(NF_2)_3]_2$, which are ethers with nitramino groups and nitroalkyl and difluoroaminoalkyl groups [50]. These compounds can be used as energetic additives in solid rocket propellants.

3.2.4.4 Preparation of C₅ Difluoroamino Compounds

Non-conjugated diolefins in the vapor or liquid phase, with one or both double bonds in the α position, react with N₂F₄ to form vicinal bis(difluoro)amines. At 313–333 K (140–160 °C), for a stoichiometric ratio of reactants and initial pressures of <1 atm, practically all the N₂F₄ is consumed in 3 h or less [51]. Liquid-phase reactions at 293–573 K (20–300 °C) and 0.2–3 MPa (2–30 atm), with or without inert diluents, are also effective. For mol ratios of N₂F₄ to diolefin of 2:1, the formation of tris- and tetrakis(difluoro)amines is favored. Lower mol ratios favor bis(difluoro)amine compound formation. Example compounds described were 1,2,4,5-tetrakis(difluoroamino)pentane, b.p. 463–465 K (190–192 °C); 3,4,5-tris(difluoroamino)-1-pentene; 1,4,5-tris(difluoroamino)-2-pentene; 4,5-bis(difluoroamino)-1-pentene, b.p. 397–398 K (124–125 °C); 3-(difluoroamino)-1,4-pentadiene; 5-(difluoroamino)-1,3-pentadiene, and 1,2,5,6-tetrakis(difluoroamino)hexane. These compounds were characterized by GC and IR and NMR spectroscopy.

3.2.4.5 Preparation of C₆ Difluoroamino Compounds

Syntheses and gas chromatographic purification of 1,1-bis(NF₂)-hexane and -heptane, 1,2-bis(NF₂)cyclohexane, 2,3-bis(NF₂)-2,3-dimethylbutane; 2,3-bis(NF₂)pentane isomers, and 1,1-, 1,2- and 2,2-bis(NF₂)phenylethane were described [52]. Elimination of HF or HNF₂ from certain organic difluoroamines yielded ketofluoroimines or trifluoroformamidines.

1,2,5,6-Tetrakis(difluoroamino)-3,4-hexanediol dinitrate can be prepared by the nitration of 1,2,4,6-tetrakis(difluoroamino)-3,4-hexanediol in CH₂Cl₂ by HNO₃ mixed with H₂SO₄ [53]. The CH₂Cl₂ layer was separated, washed, and dried and the CH₂Cl₂ removed, leaving a yellow viscous product that decomposed at 428 K (155 °C).

3.2.4.6 Preparation of C_{n>6} Difluoroamino Compounds

Preparation of TVOPA

One of the most energetic difluoroamino compounds is the trisvinoxypropyl adduct, an ether aldol compound, TVOPA, 1,2,3-tris[1,2-bis(difluoroamino)]ethoxy propane, C₉H₁₄F₁₂N₄O₃, Chemical Abstracts Service Registry Number (CAS RN) [53159-39-0]. The acronym TVOPA was derived from **tris vinoxy propyl adduct**. The compound was developed at Rohm and Haas and produced in pilot plant quantities large enough to demonstrate performance in 10-lb_m motors and several 100-lb_m motors before 1967.

TVOPA can be prepared by reacting tris(vinoxy)propane with tetrafluorohydrazine N_2F_4 in trifluorotrichloroethane:

The skeleton of the TVOPA molecule is the same as that of glycerol. Where there used to be $-\text{ONO}_2$ groups in glycerol trinitrate (GTN, also called nitroglycerin NG), there are now $-\text{OCH}(\text{NF}_2)\text{CH}_2\text{NF}_2$ groups. TVOPA was intended to be used as an energetic plasticizer in double-base propellants and plastic-bonded explosives. An optimistic process scale-up study envisioned that enough TVOPA would be prepared to support an output of 136000 kg (300000 lb_m) of propellant per month, but the use of 2,3-bis(difluoroamino)propyl acrylate (NFPA) and TVOPA as propellant ingredients would add about 85% to the cost of a conventional solid propellant motor [54].

Geminal difluoroamino compounds were evaluated as a partial or complete replacement for TVOPA, tris-1,2,3-[bis(difluoroamino)-ethoxy]propane [55]. A partial or complete replacement of the vicinal-1,2-difluoroamino plasticizer of a difluoroamino-based propellant with its structural isomer or a related structural isomer, namely, a geminal-1,1-bis(difluoroamino) compound, resulted in two beneficial effects: a marked reduction in the pressure exponent and an enhancement of the burning rate of propellant.

Preparation of SYEP

Some of the energetic plasticizers considered as alternatives for TVOPA contain nitro groups in addition to the difluoroamino groups on the alkyl rests. Examples of the geminal compounds are 2,2-bis(difluoroamino)-5,5-(dinitropentyl)formal or

4,10-[bis(difluoroamino)-1,13-difluoro-1,13-bis(dinitro)]-6,8-dioxatridecane
 2,2-bis(difluoroamino)-bis(5-fluoro-5,5-dinitro)pentyl formal
 bis[2,2-bis(difluoroamino)-5,5-dinitro-5-fluoropentoxyl]methane

or

2,2-bis(difluoroamino)-1,3-bis(fluorodinitroethoxy)propane
5,5-bis(difluoroamino)-1,9-bisdinitro-1,9-difluoro-3,7-dioxanonane

SYEP, CAS RN [7790-98-9], possesses more favorable properties, i.e., a lower m.p. and better processability characteristics than bis[2,2-bis(difluoroamino)-5,5-dinitro-5-fluoropentoxy]methane (SYFO), another candidate high-energy plasticizer. One of the methods for the production of SYEP is a nine-step procedure starting with trinitromethane (nitroform) as the starting material and involving difluorourea and difluorosulfamic acid as intermediates.

Another method for preparation of SYEP is the synthesis by difluoroamination of 1,3-bis(fluorodinitroethoxy)acetone [56]. This method depends on the availability of 1,3-bis(fluorodinitroethoxy)isopropanol, a key intermediate, from fluorodinitroethanol and epichlorohydrin. SYEP has been evaluated as a plasticizer in both PCDE, poly(1-cyano-2-difluoroamino)-2,3-epoxyethane, and polyethylene glycol (PEG) binder systems.

3.2.5 Preparation of Heterocyclic Difluoroamino Compounds

The addition of N_2F_4 to dioxadiene (a dioxane with two double bonds) gives a mixture of NF_2 compounds with two and four NF_2 groups attached to the dioxane ring. The mixture can be separated by reacting the unsaturated compound with an excess of N_2O_4 , forming a less volatile adduct, from which the more desirable tetrakis(difluoroamino)dioxane can be vacuum distilled after removing the excess N_2O_4 [57].

3-(Difluoroaminomethyl)-3-(difluoroamino)oxetane can be prepared by the reaction of 3-methyleneoxetane with N_2F_4 in Freon-113 [58]. The crude product can be redistilled by trap-to-trap distillation under vacuum using a warm water bath and identified by IR and NMR spectra. When treated with PF_5 , PF_5 -tetrahydrofuran, or $\text{BF}_3 \cdot \text{Et}_2\text{O}$, it polymerized. The polymer had a molecular weight of 9190 and was soluble in MeCN.

3.2.6 Preparation of Difluoroamino Compounds by Addition to Alkanes

Alkyl mono(difluoroamines) and bis(difluoroamines) can be prepared by reacting an alkane containing one to eight carbon atoms with tetrafluorohydrazine at 473–623 K (200–350 °C) [59]. For example, 10 cm³/min butane, 65 cm³/min tetrafluorohydrazine, and 32 cm³/min helium diluent gas were fed into a copper coil reactor heated to 573 K (300 °C) for 42 min. The product and excess reactants were collected in traps maintained at 193, 143, and 77 K (–80, –130, and –196 °C), and the contents of the –80 °C trap contained 21% 1-(difluoroamino)butane, 16% 2-(difluoroamino)butane, and 50%

1,2-bis(difluoroamino)butane. The same method was used with other alkanes, such as propane, giving *iso*-PrNF₂, *n*-PrNF₂, and MeCH(NF₂)CH₂NF₂, or isobutene, giving Me₃CNF₂, Me₂CHCH₂NF₂, Me₂C(NF₂)CH₂NF₂, CH₃CH₂CH(NF₂)Me, and PrCH(NF₂)₂.

Alkanes can be converted to difluoroaminoalkanes by irradiation with N₂F₄, producing [•]NF₂ free radicals [60]. Selectivity ratios for photodifluoramination of *n*-butane, *n*-butyl fluoride, ethyl chloride, and ethyl difluoramine were determined by analyzing the isomeric mixture of alkyl difluoroamines produced by the irradiation of N₂F₄ with these substrates. Kinetic and stoichiometric information about the photodifluoroamination process was obtained from a study of the photolysis of N₂F₄ with the simplest alkane, methane. The irradiation of N₂F₄ with propylene and isobutylene resulted not only in the substitution of NF₂ for H but the addition of F and NF₂ to the double bond. The F was found mainly on the terminal carbon atom.

The photolysis of mixtures of nitrogen trifluoride with ketones (in the temperature range 303–486 K) leads to reactions of CH₃, CF₃, C₂H₅, *iso*-C₃H₇, and *tert*-C₄H₉ radicals with nitrogen trifluoride and the formation of difluoroaminoalkanes [61]. With the smaller radicals only the abstraction of difluoroamino radicals is important, but with *iso*-C₃H₇ and *tert*-C₄H₉ both difluoroamino and fluorine abstraction occurs.

3.2.7 Preparation of Difluoroamino Compounds by Addition to Olefins (Alkenes)

Tetrafluorohydrazine dissociates readily into two difluoroamino free radicals, which can then add to C=C double or C≡C triple bonds in what is typically a free radical mechanism. Tetrafluorohydrazine readily adds to the double bond of alkenes (olefins) to give vicinal bis(difluoroamino) derivatives in good yield [26]:

The reaction of tetrafluorohydrazine with olefins, for instance reacting with ethylene while heating for 6 h at 393–403 K (120–130 °C) gave 71.5% (CH₂)₂(NF₂)₂, b.p. 344–346 K (71°–73 °C), *d*²⁰ = 1.352 g/cm³, *n*_D²⁰ = 1.3339, and some polymer on the vessel walls [25]. Similarly (at 373 K = 100 °C) with propylene the product was F₂NCH₂C(NF₂)MeH, b.p. 353–355 K (80–82 °C), *d*²⁰ = 1.248 g/cm³, *n*_D²⁰ = 1.3481. With isobutylene Me₂C=CH₂ and N₂F₄ at 353 K (80 °C) the products were a polymer and F₂NCH₂C(NF₂)Me₂, b.p. 370 K (97 °C), *d*²⁰ = 1.202 g/cm³, *n*_D²⁰ = 1.3588.

Isoalkenes and aromatic alkenes like styrene react more readily than straight-chain alkenes. Vinylidene chloride is much more active than ethene. This reaction appears to be very general, proceeding with functional olefins such as vinyl isocyanate, vinyl-*n*-butyl ether, methyl acrylate, or divinyl carbinyl acetate and haloolefins such as trichloroethylene, 1,1-difluoroethylene, and perfluoropropylene, in addition to simple olefins such as ethylene, propylene, 1,3-butadiene, and 2-heptene. The mechanism of the addition is believed to involve a free radical chain reaction similar to that postulated for the addition of bromine and polyhalogenomethanes

to olefins. The bis(difluoroamino) compounds derived from these olefins contain the vicinal bis(difluoroamino) grouping. Most of them are distillable, air-stable liquids but some have impact sensitivities worse than that of TNT. Difluoroamino compounds prepared by the addition of N_2F_4 to $>\text{C}=\text{C}<$ compounds have been evaluated as plasticizers for nitrocellulose [62].

3.2.8 Preparation of Difluoroamino Compounds by Addition to Acetylenes (Alkynes)

Only 1 mol N_2F_4 is added to alkynes, for examples, to 2-hexyne, with the formation of a mixture of addition products and products of the substitution of the α -H atom for the NF_2 group:

gem-Bis(difluoroamino) compounds of the type $\text{R}'\text{C}(\text{NF}_2)_2\text{CH}_2\text{R}''$ can be prepared by treating NHF_2 with an acetylene of the type $\text{R}'\text{C}\equiv\text{CR}''$ in the presence of a strong acid catalyst, e.g., BF_3 , $\text{BF}_3\text{-H}_3\text{PO}_4$ complex, and SO_3 fuming H_2SO_4 [63]. When 1-hexyne was added dropwise with external cooling to a refluxing mixture of 7 g NHF_2 and 15 mL conc. H_2SO_4 at 258 to 253 K (-15 to -20°C), an upper layer separated from the H_2SO_4 . After 4 h, excess NHF_2 was removed, and a liquid product containing 2,2-bis(difluoroamino)-hexane and 3-hexyne was obtained. Under the same conditions 1,4-pentadiyne gave 2,2,4,4-tetrakis(difluoroamino)pentane.

3.3 Physical Properties of Difluoroamino Compounds

Surprisingly, it was found to be difficult to find a systematic and complete source for physical properties of difluoroamino compounds, arranged by the length and structure of the alkyl rest (methyl, ethyl, *n*-propyl, isopropyl, and so on) and by the number of difluoroamino groups in the molecule. For example, the physical properties of bis(difluoroamino) alkanes are listed in Table 4.

Table 4: Physical properties of bis(difluoroamino) alkanes.

Compound	Density, ρ , g/cm ³		Sound velocity, c mm/ μs	Coefficient of expansion 1/ $^\circ\text{C}$	Heat capacity

Data source: [64]

3.3.1 Physical Properties of C₁ Difluoroamino Compounds

The physical properties of *N,N*-difluoroaminomethane compounds are listed in Table 5.

Table 5: Physical properties of *N,N*-difluoroaminomethane compounds

Compound	H ₃ CNF ₂	H ₂ C(NF ₂) ₂	HC(NF ₂) ₃	C(NF ₂) ₄	References

CAS RN	753-58-2	18338-50-6	121832-14-2	17125-65-4	
Molecular mass	67.0380	118.03	169.03	220.0247	[65]
Freezing point	158.3 K = −114.8 ± 0.3 °C			259.6 K = −13.5 °C	[27]
Boiling point	257.1 K = −16.0 °C	309 K (36 °C) (predicted)	341 K (68 °C) (predicted)	313 K = 40 °C	[27]
Density	1.099 ± 0.0005 g/cm ³ at 253 K	1.451 ± 0.06 g/cm ³ (predicted)	1.692 ± 0.06 g/cm ³ (predicted)	1.748 g/cm ³	[27]
Vapor pressure	see equation below				
Enthalpy of formation, liquid				−16.7 ± 11 kJ/mol = −4.0 ± 2.8 kcal/mol	[66]
Heat of vaporization	23.5 kJ/mol				[65]
Heat of vaporization	22.9 kJ/mol = 5.48 kcal/mol at NBP				[27]

Some more detailed additional physical properties of CH₃NF₂ are given in what follows [27]. The vapor pressure of CH₃NF₂ over the range 80 to 204 K = −193 to −69 °C can be expressed by

$$\log P_{10} = 5.6731 - 755.13/T - 56631/T^2$$

where *P* is the pressure in cm Hg and *T* is the temperature in kelvin. The temperature was determined accurately to within ±0.15 °C and the pressure to within ±0.005 cm Hg. The b.p. at 760 mm Hg was 257.1 K = −16.0 °C + 01 °C and the m.p. was 158.3 K = −114.8 °C ± 0.3 °C. The density at 253 K = −20 °C was 1.099 ± 0.0005 g/cm³. The latent heat of vaporization at the normal b.p. was 22.9 kJ/mol = 5.48 kcal/mol.

The IR spectra of gaseous CH₃NF₂ and CD₃NF₂ and of solid CH₃NF₂ were measured and discussed in terms of the symmetry of Point Group C_s (Figure 1 and 2) [67]. The

Figure 1: IR spectrum of solid *N,N*-difluoroaminomethane. (Republished and modified from [67], with permission of © 1966 American Institute of Physics; permission conveyed through Copyright Clearance Center, Inc.)

Figure 2: IR spectrum of *N,N*-difluoroaminomethane vapor. (Republished and modified from [67], with permission of © 1966 American Institute of Physics; permission conveyed through Copyright Clearance Center, Inc.)

unsymmetrical methyl vibrations, which are degenerate under the local C_{3v} symmetry of the group, were found to undergo splitting of smaller magnitude than in analogous compounds of C_s overall symmetry. The two nearly degenerate components of each of these motions appeared to be coupled through rotation. Figure 2 is a composite of five different images. The five IR spectra of CH_3NF_2 vapor in Figure 2 were measured with several sample cells of different optical path lengths, and the absorption/transmission scale of each segment is different.

Similarly, the IR spectrum of the perfluorinated compound CF_3NF_2 vapor was recorded in the region of 250 to 2000 cm^{-1} and also interpreted in terms of C_s symmetry of the molecule [68]. It was possible to identify 13 bands with fundamental vibrations.

Bis(difluoroamino)methane, $\text{H}_2\text{C}(\text{NF}_2)_2$, is the simplest geminal difluoroamino compound. The chemical name for $\text{H}_2\text{C}(\text{NF}_2)_2$ used in Chemical Abstracts (CA) is methanediamine, *N,N,N',N'*-tetrafluoro-. The predicted b.p. is 309 K (36°C) and the predicted density is $1.451 \pm 0.06\text{ g/cm}^3$, but the accuracy of those predictions is unknown.

The fourth column in the following table, Table 6, on fluorodifluoroamino-methane compounds is identical with the fourth column in the previously discussed Table 5, but the first three columns are for difluoroamino compounds where the C—H has been replaced by C—F.

To calculate the heat of formation of bis(difluoroamino)difluoromethane (Compound H), two numbers for the heat of explosion were available from the literature. Averaging these two numbers, and assuming a heat of formation ΔH_f^{298} of $-922.6\text{ kJ/mol} = -220.5\text{ kcal/mol}$ for $\text{CF}_4(\text{G})$, one obtains an enthalpy of formation ΔH_f^{298} of $-449.8\text{ kJ/mol} = -107.5 \pm 5\text{ kcal/mol}$ for $\text{F}_2\text{C}(\text{NF}_2)_2$ vapor and $-563.2\text{ kJ/mol} = -134.6 \pm 2.5\text{ kcal/mol}$ for $\text{F}_2\text{C}(\text{NF}_2)_2$ liquid. These numbers differ from those listed in Table 6.

The vapor pressure of perfluoromethylamine from the mp at 151 to 198 K (-122.1 to -75°C) follows the equation

$$\log p = 7.47 - 901.0/T$$

where p is the vapor pressure in mm Hg and T is the temperature in kelvin. The heat of vaporization is 17.2 kJ/mol (4.12 kcal/mol) and the Trouton constant is 21.0 [71].

The vapor pressure of bis(difluoroamino)difluoromethane can be expressed by the equation

$$\log p = 7.653 - 1149/T$$

where p is the vapor pressure in mm Hg and T is the temperature in kelvin [28]. The b.p. is $241 \pm 1\text{ K} = -32 \pm 1^\circ\text{C}$.

The vapor pressure of tris(difluoroamino)fluoromethane in the temperature range 190–310 K can be calculated from

$$\log p = 7.6484 - (1328.8/T)$$

Table 6: Physical properties of *N,N*-difluoroaminoperfluoromethane compounds.

^aThis number may not be very accurate.

where p is the vapor pressure in mmHg and T is the temperature in kelvin [29]. The heat of vaporization is 25.4 kJ/mol (6.08 kcal/mol). The density at 298 K = 25 °C is 1.56 g/cm³. The density as a function of temperature in the temperature range 233–353 K (−40 to 80 °C) can be calculated from

$$\rho = 1.622 - 30.020 \times 10^{-4}t - 1.701 \times 10^{-6}t^2 - 9.732 \times 10^{-8}t^3$$

where ρ is the density in g/cm³ and t is the temperature in °C. Tris(difluoroamino)fluoromethane, FC(NF₂)₃, is also known under the code name Compound R.

The enthalpy of formation of liquid tris(difluoroamino)fluoromethane is −220 ± 8.3 kJ/mol = −52.5 ± 2.0 kcal/mol. The enthalpy of formation of liquid tetrakis(difluoroamino)methane is −16.7 ± 11 kJ/mol = −4.0 ± 2.8 kcal/mol and that of tetrakis(difluoroamino)methane vapor is +10.9 ± 11 kJ/mol = +2.6 ± 2.8 kcal/mol.

Tetrakis(difluoroamino)methane, octafluoromethanetetramine, Compound Delta, C(NF₂)₄, CAS RN [17125-65-4], is an analog of tetranitromethane where all oxygens have

been replaced by fluorine. This compound was evaluated as a liquid oxidizer, similar to TNM, and was also mixed with TNM. Mixtures of tetrakis(difluoroamino)methane and TNM have been considered as storable oxidizers, a storable version of FLOX [1, 2].

The geometric structures of the CF_3NF_2 and $(\text{CF}_3)_2\text{NF}$ molecules were determined from electron diffraction and microwave spectroscopy data [72]. The Raman and IR spectra of both compounds were recorded in the liquid and vapor states and assigned for C_s symmetry. Normal coordinate analyses were performed using extensive transfer of force constants in the series $(\text{CF}_3)_n\text{NF}_{3-n}$. In this series the N—F bond lengths do not depend on n within the experimental error limits. The N—C bond lengths decreased and the corresponding force constants increased with increasing n . It was attempted to explain this trend on the basis of a simple bonding model.

The enthalpy of formation of trifluoromethoxy difluoroamine, F_3CONF_2 , was calculated from the heat of explosion of mixtures of hydrogen and trifluoromethoxy difluoroamine as $-791.2 \pm 3.3 \text{ kJ/mol}$ ($-189.1 \pm 0.8 \text{ kcal/mol}$) based on the NBS Technical Note 270-1 value for HF (aq.) [73].

The ^{18}F NMR spectrum of CF_3NF_2 made by fluorination of KSCN and separation from SF_6 consisted of a broad peak at ϕ 84.1 and another broad peak at -18.5 [74]. The relative area ratio of the two peaks was 3.11 : 2.0.

Another C_1 NF compound which is of interest as an intermediate for the synthesis of other NF compounds is PFG, pentafluoroguanidine, CAS RN [10051-06-6]:

PFG is a liquid with a freezing point of 113 K (-160°C), a b.p. of 271 K (-2°C), a density of 1.70 g/cm^3 (below the b.p.), and an enthalpy of formation ΔH_f^{298} of $+79 \text{ kJ/mol} = +18.9 \text{ kcal/mol}$ in the liquid state, $+101 \text{ kJ/mol} = +24.2 \text{ kcal/mol}$ in the vapor state, and a heat of evaporation of $22.2 \text{ kJ/mol} = 5.3 \text{ kcal/mol}$. The vapor pressure of PFG in the temperature range of 100–253 K can be calculated from

$$\log p = 7.322 - (1203/T)$$

where p is the vapor pressure in mm Hg and T is the temperature in kelvin. The heat of vaporization is 23 kJ/mol (5.50 kcal/mol). The IR spectrum of $(\text{NF}_2)_2\text{C}=\text{NF}$ contained bands at 6.11 (m), 7.41 (s), 7.98 (s), 8.22 (s), 8.45 (sh), 9.74 (s), 10.62 (s), and 13.60 (s) μm . It is extremely sensitive to shock and has been the cause of numerous accidents during the attempted synthesis of other difluoroamino compounds starting with PFG as the fluorinating agent.

PFG can be made by direct fluorination with nitrogen-diluted fluorine gas of guanidinium monofluoride powder in dilution with a large amount of sodium fluoride [75]. PFG boils at 272.0 K (-1.1°C) and is extremely explosive.

3.3.2 Physical Properties of C_2 Difluoroamino Compounds

The physical properties of mono-, bis-, and tris(*N,N*-difluoroamino)ethane compounds are listed in Table 7.

Table 7: Physical properties of mono-, bis-, and tris(difluoroamino)ethane compounds.

Compound	H ₃ CCH ₂ NF ₂	H ₃ CCH(NF ₂) ₂	H ₃ CC(NF ₂) ₃	F ₂ NCH ₂ CH ₂ NF ₂	References

Enthalpy of formation, vapor				−172 ± 17 kJ/mol = −41 ± 4 kcal/mol	[66, 69]

The vapor pressure of C₂H₅NF₂ over the range 241 to 258.7 K (−32 to −14.4 °C) can be expressed by the following equation [27]:

$$\log P_{10} = 5.7005 - 856.30/T - 70345/T^2$$

where P is the pressure in cm Hg and T is the temperature in kelvin. Temperature measurements were made to ±0.1 °C, and the pressure was measured to ±0.005 cm Hg. The b.p. was at 288.0 ± 0.1 K = 14.9° ± 0.1 °C. The mp was at 122.8 ± 0.3 K = −150.3 ± 0.3 °C. The density of C₂H₅NF₂ over the range 238.3 to 258.4 K (−34.8 to −14.7 °C) can be expressed by

$$\log D_{10} = -0.41505 + 177.14/T - 16889/T^2$$

where D is the density in g/cm³ and T is the temperature in kelvin. The density at 273 K = 0 °C was 1.0165 g/cm³.

The reaction of fluorine with either trifluoroacetonitrile or pentafluoropropionitrile at 195 K (−78 °C) in the presence of activated cesium fluoride produced the corresponding perfluoroalkyl difluoramines smoothly: C₂F₅NF₂, CAS RN [354-80-3] and C₃F₇NF₂, CAS RN [423-32-5] [74].

Perfluoroethylamine, $\text{C}_2\text{F}_5\text{NF}_2$, boils at 237 K (-36°C) and solidifies to a glass near 102 K (-171°C) [71]. The vapor pressure of $\text{C}_2\text{F}_5\text{NF}_2$ in the range of 171 to 236 K (-102 to -37°C) is given by the equation

$$\log p = 7.435 - 1088/T$$

where p is the pressure in mm Hg and T is the temperature in kelvin. The heat of vaporization is 20.8 kJ/mol (4.98 kcal/mol), and the Trouton constant is 20.8. The b.p. of $(\text{CF}_2\text{NF}_2)_2$ is 268.0 to 268.6 K (-5.1 to -4.5°C).

3.3.3 Physical Properties of C_3 Difluoroamino Compounds

The physical properties of mono- and bis-(difluoroamino)propane compounds are listed in Table 8. *n*-Difluoroaminopropane, *N,N*-difluoropropylamine, $\text{H}_3\text{CCH}_2=\text{CH}_2\text{NF}_2$, is also called 1-propanamine, *N,N*-difluoro- in the CA index.

Table 8: Physical properties of difluoroaminopropane compounds.

^aPredicted

Of all the C_3 difluoroamines, the literature references the compounds isopropyldifluoroamine and 1,2-DP the most. Another C_3 difluoroamino compound of interest is tris(difluoroaminomethyl)amine, $(\text{F}_2\text{NCH}_2)_3\text{N}$, with a b.p. of 166°C and a density of 1.378 g/cm^3 at 291 K = 18°C . Perfluoropropylamine, $\text{C}_3\text{H}_7\text{NF}_2$, boils at 273 K = 0°C and solidifies at 105 K (-168°C).

The refractive indices of RNF_2 and other liquid compounds are often used to verify the purity of a substance. The refractivities of the NF_2 group and of the N–F bond in 14 liquid organic NF_2 derivatives were compared using experimental values of n_D^{20} and d^{20} as well as previously published group and bond additivity refractivity data [76]. For mono(difluoroamino) alkanes, the NF_2 refractivity was $R_{\text{NF}_2} = 4.97$ and the

refractivity of the N atom was $R_N = 3.35$. For vicinal bis(difluoroamino)- and functional mono(difluoroamino) derivatives, refractivities were $R_{NF_2} = 5.27 \pm 0.06$ and $R_N = 3.65$. The N–F bond refractivity does not depend on the structure of the R alkyl rest $RN-F = 2.14 \pm 0.02$.

3.3.4 Physical Properties of C₄ Difluoroamino Compounds

The b.p. of butyldifluoroamines is as follows: *n*-BuNF₂, b.p. = 354–357 K = 81–84 °C; *iso*-BuNF₂, b.p. = 334 K = 61 °C; *sec*-BuNF₂, b.p. = 359 K = 86 °C.

The standard enthalpy of formation of 2,2-bis(difluoroamino)butane liquid is $-211.5 \pm 5 \text{ kJ/mol} = -50.86 \pm 1.2 \text{ kcal/mol}$, and that of its 2,3 stereoisomer is $-233 \pm 5 \text{ kJ/mol} = -55.77 \pm 1.2 \text{ kcal/mol}$. The density of the latter compound is 1.212 g/cm^3 .

Tetrakis(difluoroamino)tetrahydrofuran, C₄H₄N₄F₈O, with a molecular mass of 276.09 g/mol is a liquid at room temperature. The standard enthalpy of formation of liquid tetrakis(difluoroamino)tetrahydrofuran is $-308 \pm 21 \text{ kJ/mol} = -73.5 \pm 5 \text{ kcal/mol}$ [66, 69]. The PEPCODED.DAT data file [7] lists $-266 \text{ cal/g} = -73.4 \text{ kcal/mol} = -307 \text{ kJ/mol}$. The density is 1.604 g/cm^3 . Other sources give ΔH_f^{298} of this compound as $-286 \text{ kJ/mol} = -68.3 \pm 3.2 \text{ kcal/mol}$, so there is some discrepancy among the different data sources.

1,1,3-Tris(difluoroamino)butane is a liquid at room temperature. The standard enthalpy of formation of liquid 1,1,3-tris(difluoroamino)butane is $-214 \pm 12 \text{ kJ/mol} = -57.7 \pm 3 \text{ kcal/mol}$, and the heat of combustion is $3424 \text{ kJ/mol} = 810.48 \text{ kcal/mol}$. 1,3,3-Tris(difluoroamino)butane boils at 312 K at 1.3 kPa (39 °C at 10 mm Hg). Tetrakis(difluoroamino)butane has an enthalpy of formation of $-240.5 \text{ kJ/mol} = -57.49 \text{ kcal/mol}$ and a density of 1.54 g/cm^3 .

Many energetic compounds contain both nitro or nitramide and difluoroamino groups in their molecules. An example is 1,1,3,5,5-pentanitro-1,5-bis(difluoroamino)-3-azapentane, F₂N(O₂N)₂CCH₂N(NO₂)CH₂C(NO₂)₂NF₂, C₄H₄N₈O₁₀F₄, DFAP, which can be obtained through the reaction of bis(2,2-dinitroethyl)nitramine with NF₂OSO₂F and has an extremely high density for an acyclic compound of 2.045 g/cm^3 [77]. Theoretical density functional theory (DFT) calculations were performed to study the effect of substitution of some or all of the nitro groups by nitroxy or difluoroamino groups. The predicted heat of formation ΔH_f^{298} of Compound 5 which had all $-\text{NO}_2$ replaced by $-\text{NF}_2$ was worse than that of the baseline DFAP, Compound 3. Compound 7, which had all NO₂ groups on the carbon replaced by $-\text{ONO}_2$ groups with only the nitramine NO₂ on Atom 3 remaining in place, had the lowest (worst) ΔH_f^{298} of all seven compounds studied. The heats of explosion did not parallel the heats of formation. The highest predicted heat of explosion was for Compound 4, which had all $-\text{NO}_2$ groups in the two alkyl rests replaced by $-\text{NF}_2$ groups but retained the $-\text{NO}_2$ group on the nitramine on Atom 3. The general trend was that Q increased because the ONO₂ and NO₂ groups were replaced by NF₂ groups.

3.3.5 Physical Properties of C_6 Difluoroamino Compounds

The standard heat of formation of liquid 1,2-bis(difluoroamino)4-methylpentane at 298.15 K is $-251 \text{ kJ/mol} = -60.09 \text{ kcal/mol}$, the heat of vaporization is $44 \text{ kJ/mol} = 10.51 \text{ kcal/mol}$, and the standard heat of formation of the vapor is $-207 \text{ kJ/mol} = -49.58 \text{ kcal/mol}$ [78–80]. The N–F thermochemical bond energy in this compound was $280 \text{ kJ/mol} = 67 \text{ kcal/mol}$, about the same as the N–F bond energy in NF_3 and N_2F_4 .

The standard heat of formation of the isomer liquid 2,2-bis(difluoroamino)4-methylpentane at 298.15 K is $-275 \text{ kJ/mol} = -65.61 \pm 0.45 \text{ kcal/mol}$, and its density is 1.155 g/cm^3 . The standard heat of formation of the isomer liquid 2,3-bis(difluoroamino)-4-methylpentane at 298.15 K is $-286 \text{ kJ/mol} = -68.27 \pm 0.76 \text{ kcal/mol}$, and its density is 1.150 g/cm^3 .

The b.p. of 1,1-bis(difluoroamino)cyclohexane was 318 K at 0.8 kPa (45°C at 6 mm Hg). The heat of combustion of 1,1-bis(difluoroamino)cyclohexane was $4288 \pm 2 \text{ kJ/mol} = 1024.9 \pm 0.5 \text{ kcal/mol}$ [81]. Based on this number, the enthalpy of formation was $-220 \pm 2 \text{ kJ/mol} = -52.5 \pm 0.5 \text{ kcal/mol}$, and the heat of vaporization was $10.6 \pm 0.2 \text{ kcal/mol}$. The bond energy of the N–F bond was $286 \text{ kJ/mol} = 68.4 \text{ kcal/mol}$.

A less common difluoroamino compound is di[tris(difluoroamino)propyl] ether, $\text{C}_6\text{H}_8\text{F}_{12}\text{N}_6\text{O}$ with a molecular mass of 408.178 g/mol , an enthalpy of formation of $-538 \pm 48 \text{ kJ/mol} = -128.7 \pm 10 \text{ kcal/mol}$, and a density of 1.65 g/cm^3 .

3.3.6 Physical Properties of $C_{n>6}$ Difluoroamino Compounds

The heat of combustion of liquid 1,1-bis(difluoroamino)heptane was measured, and the standard enthalpy of formation of the liquid at 298.15 K derived from this number was $-271 \text{ kJ/mol} = -64.8 \text{ kcal/mol}$, and the standard enthalpy of formation of the vapor was $-221 \text{ kJ/mol} = -52.8 \text{ kcal/mol}$ [82]. Its density was 1.18 g/cm^3 . The N–F thermochemical bond energy in this compound was $280 \text{ kJ/mol} = 67 \text{ kcal/mol}$, about the same as the N–F bond energy in NF_3 and N_2F_4 .

3.3.6.1 Physical Properties of TVOPA

TVOPA is a colorless liquid that freezes at $<243 \text{ K}$ ($<-30^\circ\text{C}$). The density of TVOPA is 1.54 g/cm^3 at 301 K (28°C). Other sources give a density of 1.535 g/cm^3 . The viscosity of TVOPA is 33 cPs at 303 K (30°C).

The heat of combustion of TVOPA in oxygen was determined to be $6749 \pm 15 \text{ kJ/mol}$ ($1613 \pm 3.5 \text{ kcal/mol}$) [83]. From this value and from previous data, the ΔH_f^{298} was calculated to be $-910 \pm 23 \text{ kJ/mol}$ ($-217.4 \pm 5.5 \text{ kcal/mol}$). The difference between this and other reported results may be caused by varying amounts of methylene chloride adhering to the sample. A year later, the heat of combustion of purified TVOPA in oxygen was once more measured by rotating bomb calorimetry [84]. The derived measured heat of formation of purified TVOPA was -871 kJ/mol (-208.1 kcal/mol).

3.3.6.2 Physical Properties of SYEP

2,2-bis(difluoroamino)-1,3-bis(fluorodinitroethoxy)propane, 5,5-bis(difluoroamino)-1,9-bisdinitro-1,9-difluoro-3,7-dioxanonane, SYEP, CAS RN [7790-98-9], $C_7H_8O_{10}N_6F_6$,

is a colorless liquid with a m.p. of 275 K (36 °F), a density of 1.937 g/cm³ (0.0611 lb/in.³), and an enthalpy of formation of -295.4 kJ/mol = -70.6 kcal/mol = -601 cal/g. The oral toxicity LD50 in rats was 3500 mg/kg. SYEP was intended as an energetic plasticizer but is apparently no longer in production.

SYEP possesses more favorable properties, i.e., lower mp and better processability characteristics, than bis[2,2-bis(difluoroamino)-5,5-dinitro-5-fluoropentoxy]methane (SYFO), another candidate high-energy plasticizer.

3.3.7 Mixtures with Difluoroamino Compounds

Mixtures of aliphatic difluoroamino compounds, such as 1,2-bis(difluoroamino)ethane $C_2H_4(NF_2)_2$, tris(difluoroamino)propane $C_3H_5(NF_2)_3$, tetrakis(difluoroamino)tetrahydrofuran, tetrakis(difluoroamino)butane $C_4H_6(NF_2)_4$, and pentakis(difluoroamino)pentane $C_5H_7(NF_2)_5$ with tetranitromethane have been patented as rocket propellant oxidizers [85]. The inventor failed to verify that the two liquids are miscible over the entire range of mixture ratios and will not segregate on cooling.

Mixtures of dinitrogen tetroxide (NTO) and 1,2-bis(difluoroamino)-2-methylpropane (IBA) or tris(difluoroamino)fluoromethane have been tested as storable oxidizers for pre-packaged propulsion systems [86]. The advantage of diluting the RNF_2 compound with NTO is that it greatly reduces the shock sensitivity of the undiluted RNF_2 compound.

3.3.8 Thermodynamic Properties of Difluoroamino Compounds

Thermodynamic properties such as the heats (enthalpies) of formation of difluoroamino compounds tend to be more negative than those of analogous nitro derivatives, but quantitative measures of performance (such as specific impulse of rocket propellant combustion) offer a more valid comparison of the energetics of difluoroamino derivatives. The lower molecular mass of HF compared to CO_2 as the reaction product is part of the reason for the higher specific impulse.

If fluorinated oxidizers are used in combination with metal fuel ingredients (e.g., aluminum or boron), producing more volatile, lower-molecular-weight combustion products, such as boron oxyfluoride (BOF) (rather than simple oxides like B_2O_3 produced solely by oxygenated oxidizers) also result in higher specific impulse. RNF_2 compounds also have higher densities than RNO_2 compounds. The following sections contain information on both experimental and theoretical determination of the thermodynamic properties of difluoroamino compounds, as well as those containing additional explosophoric groups in the molecule.

3.3.8.1 Experimental Determination of Thermodynamic Properties of Difluoroamino Compounds

Because many difluoroamino compounds are potentially detonable and many decompose in an uncontrolled manner, it is difficult to determine the heats of combustion and enthalpies of formation of these compounds by calorimetric methods. Some of the measured heats of combustion reported in the literature vary widely, depending on the conditions during combustion.

The heat of decomposition of CF_3NF_2 was -451.4 ± 1.5 cal/g. The enthalpy of formation $\Delta H_f^{298.15}$ (G) was determined to be -707 ± 2.5 kJ/mol (-169.0 ± 0.6 kcal/mol) by measuring its energy of decomposition to CF_4 (G), N_2 (G), and F_2 (G) in a nickel bomb and static calorimeter [87]. A gaseous mixture of C_2N_2 and NF_3 was used to trigger the reaction. The experimental $\Delta H_f^{298.15}$ was compared with that calculated from additive bond energies, which gave -724.7 kJ/mol (-173.2 kcal/mol) (uncorrected).

The heat of formation of tetrakis(difluoroamino)methane (Compound Delta) was determined by the heat of explosion measurements to be $+10.9 \pm 11.7$ kJ/mol ($+2.6 \pm 2.8$ kcal/mol), as in [88]. This result correlated well with previous work on $FC(NF_2)_3$ and $F_2C(NF_2)_2$. An estimate of -686 kJ/mol (-164 kcal/mol) was derived for $CF_3(NF_2)(G)$. A heat of combustion of 1,2,3-tris[1,2-bis(difluoroamino)ethoxy]propane (TVOPA) in oxygen showed a strong trend to low values with increasing residual solvent. By extrapolation to zero solvent, a heat of formation of -910 ± 15 kJ/mol (-217.4 ± 3.5 kcal/mol) was derived for TVOPA. The heat of combustion of poly[1,2-bis(difluoroamino)epoxy propane] (P-BEP) in oxygen was determined by rotating bomb calorimetry. Prolonged stripping of the sample under vacuum resulted in satisfactorily low residual solvent. The heat of combustion in oxygen was 15.814 kJ/g (3.629 kcal/g). If one assumes a molecular mass of exactly 100 g/mol and the empirical composition $C_{2.238} H_{3.240} O_{0.898} N_{1.094} F_{2.114}$, the derived heat of formation would be -200 ± 3 kJ/mol (-47.8 ± 0.7 kcal/mol).

The heats of formation of 1,2,3-tris[1,2-bis(difluoroaminoethoxy)]propane, TVOPA, and CF_3ONF_2 (G) were determined by combustion in oxygen in a rotating bomb calorimeter and found to be -870.7 ± 12.1 and -791.2 ± 3.3 kJ/mol (-208.1 ± 2.9 and -189.1 ± 0.8 kcal/mol), respectively [89]. Prior to determining the heat of reaction, solvent had to be removed from TVOPA and CF_3ONF_2 had to be purified. Undiluted TVOPA detonated under combustion bomb conditions and had to be

diluted. Other sources list the heat of formation of TVOPA as -867 ± 12.4 kJ/mol (-207.19 ± 2.96 kcal/mol) [66, 69].

Table 9 gives the measured enthalpies of reaction (heat of explosion) of three gaseous difluoroaminomethanes and PFG and the enthalpies of formation derived therefrom [70].

Table 9: Heat of explosion and enthalpies of formation of three gaseous difluoroaminomethanes and perfluoroguanidine.

Compound name	Gross formula	Alternate compound name	ΔE_{expl}	ΔH_{expl}	ΔH_f
			kcal/mol		
Bis(difluoroamino)-difluoromethane	CF_6N_2	Hexafluoromethanediamine	-115.5	-114.3	-108.7
Tris(difluoroamino)-fluoromethane	CF_7N_3	Heptafluoromethanetriamine	-177.0	-175.3	-47.7
Tetrakis(difluoroamino)-methane	CF_8N_4	Octafluoromethanetetraamine	-225.9	-223.5	+0.5
Perfluoroguanidine	CF_5N_3	Pentafluoroguanidine	-247.2	-246.0	+23.0

Data source: [70]

From calorimetric measurements of the energies of explosion, the enthalpies of formation of some fully fluorinated amines in the gas state were derived as listed in Table 10, and the eventual deviations of these values from those calculated from additive standard bond-energy terms were discussed [70].

Table 10: Enthalpies of formation of difluoroamino compounds in gas phase.

Compound	Enthalpy of formation	
	kJ/mol	kcal/mol
$\text{F}_2\text{C}(\text{NF}_2)_2$	-455	-108.7
$\text{FC}(\text{NF}_2)_3$	-199.6	-47.7
$\text{C}(\text{NF}_2)_4$	+2.1	+0.5
$\text{FN}=\text{C}(\text{NF}_2)_2$	+96	+23.0
$(\text{F}_2\text{N})_2\text{CFNFCF}(\text{NF}_2)_2$	-353	-84.4

Data source: [70]

The PEPCODED.DAT data file of [7] contained enthalpy of formation data and a few density data for several difluoroamino compounds. These data were converted to SI units and are summarized in Table 11. Some of the compounds had more than one entry, and it was not possible to determine which were the more correct data, so we listed them all. See also [90].

Table 11: Enthalpies of formation and densities of difluoroamino compounds.

Compound name	CHNOF	Mol. mass g/mol	Enthalpy of formation, ΔH_f^{298}			Density g/cm ³
			cal/g	kcal/mol	kJ/mol

3.3.8.2 Theoretical Computation of Thermodynamic Properties of Difluoroamino Compounds

The thermodynamic properties of simple difluoroaminoalkanes can be predicted based on quantum-mechanical calculations. An attempt was made to calculate the entropies, heats of formation, and bond dissociation energies of alkyl difluoroamines and fluorides for which experimental or published calculated data were lacking [91]. The estimated enthalpies of formation and entropies of alkyl difluoroamines and fluorides, and bond dissociation energies for R–NF₂ and R–F molecules (R = Me, Et, *iso*-Pr, *tert*-Bu, and trifluoromethyl) were published, but the foreign publication was not accessible to the author.

The enthalpies of formation of a series of polyatomic molecules containing –NF₂ and/or –NO₂ groups were computed using the isodesmic procedure of Pople et al. at the self-consistent field (SCF) level [92, 93]. An excellent correlation between the predicted enthalpies of formation and the corresponding available experimental (calori-

metric) data was achieved. It was found that $-\text{NO}_2$ and $-\text{NF}_2$ groups had significant and comparable destabilizing effects on hydrocarbon compounds.

The well-known simple Benson method predicts the enthalpies of formation of gaseous compounds by adding contributions from individual bonds. Expanding on this method, a similar additive method was developed for estimating the gaseous enthalpies of formation of energetic molecules containing NO_2 and/or NF_2 groups, and its accuracy was checked against measured values taken from previously published sources [94].

Polynitrocubanes have already been described in *Encyclopedia of Oxidizers*, in the chapter “Higher Nitroaliphatic Compounds,” as promising high-energy-density materials (HEDMs).

In analogy, polydifluoroaminocubanes and polydifluoroaminoadamantanes were expected to have high density and high explosive power.

The enthalpies of formation for a series of polydifluoroaminocubanes were calculated using DFT, Hartree-Fock, and MP2 methods, as well as semi-empirical methods [95]. The cubane skeleton was not broken in the process of designing isodesmic reactions, i.e., the cubane skeleton was chosen for a reference compound. The contribution of difluoroamino group to the heat of formation deviated from group additivity rules. The semi-empirical MO (Modified Neglect of Diatomic Overlap = MNDO, Austin Model 1 = AM1, and PM3) methods did not produce accurate and reliable results for the enthalpies of formation. It was found that the enthalpies of formation decreased dramatically initially and then gradually with each difluoroamino group attached to the cubane skeleton. The distance between difluoroamino groups influenced the values of enthalpies of formation. The NF_2 group can rotate freely around the C–N bond. Similar observations were made when calculating the predicted enthalpies of formation of polydifluoroaminoadamantanes with increasing numbers of $-\text{NF}_2$ groups attached to the cage skeleton [96].

A theoretical study of the effect of progressive replacement of $-\text{NO}_2$ groups in 1,1,1,3,5,5,5-heptanitro-3-azapentane by $-\text{NF}_2$ groups or $-\text{O}-\text{NO}_2$ groups showed that (depending on the computational method and level used) the predicted enthalpy of formation decreased incrementally from $+98 < \Delta H < +104$ kJ/mol for 1,1,1,3,5,5,5-heptanitro-3-azapentane to $-150 < \Delta H < -160$ kJ/mol for 1,1,1,3,5,5,5-hepta(difluoroamino)-3-azapentane [97].

3.3.9 Molecular Structure of Difluoroamino Compounds

3.3.9.1 Molecular Structure of Linear Difluoroamino Compounds

The molecular structures of difluoroamino compounds are often compared to those of the corresponding nitro compounds that contain oxygen in the place of the fluorines.

In designing energetic molecules, it can be advantageous to include some difluoroamino ($-\text{NF}_2$) groups along with the usual nitro ($-\text{NO}_2$) groups [98]. Although the $-\text{NF}_2$ groups can have the desirable effects of increasing the density, there may also

be a decrease in the amount of energy released during decomposition. The overall result is likely to be improved energetic performance. Although C–NF₂ and N–NF₂ bonds are slightly stronger than C–NO₂ and N–NO₂ bonds, the lack of stability of difluoramines is known to be a challenge to propellant chemists. Molecules of the type R_aR_bN–NF₂ may have a tendency to lose F[–]. However, this can be prevented by making R_a and R_b sufficiently electron-attracting and by structuring the molecule so that there are no hydrogens on carbons bearing –NF₂ groups. It is also advisable to not have –NO₂ and –NF₂ groups on the same carbon atom, since this leads to a destabilizing weakening of both the C–NO₂ and C–NF₂ bonds.

The structure of methyldifluoroamine, CH₃NF₂, was determined by gas-phase electron diffraction augmented by rotational constants from microwave spectroscopy and by results from molecular orbital calculations [99]. The structural results were consistent with C_s symmetry for a molecule with staggered bonds. The experimental bond distances and bond angles with estimated 2σ uncertainties were C–H = 1.104/1.124(5) Å (average value), N–F = 1.406/1.408(2) Å, C–N = 1.467/1.469(6) Å, ∠ C–N–F = 104.1(2)°, ∠ F–N–F = 101.7(2)°, ∠ N–C–H_{anti} = 109.9(11)°, ∠ N–C–H_{gauche} = 106.5(10)°, ∠ H_{gauche}C–H_{gauche} = 110.6(28)°; the subscripts indicate orientation with respect to the lone nitrogen pair. The bond lengths and bond angles of a family of fluoroamino compounds, including two methyl fluoro amines as determined from microwave spectra and electron diffraction, are summarized in Table 12.

Table 12: Bond lengths and bond angles of fluoroamino compounds.

Compound	Unit	H ₂ NF	HNF ₂	NF ₃			MeNF ₂		Me ₂ NF
Method:			MW	MW	MW		MW	ED/MW	MW
r(X–N)	Å	1.0225(3)	1.026(2)				1.467(6)	1.449(5)	1.462(7)
r(N–F)	Å	1.4329(3)	1.400(2)	1.365(2)	1.371		1.406(2)	1.413(5)	1.447(6)
∠ X–N–F	°	101.08(7)	99.8(2)				104.1(2)	104.6(3)	103.6(5)
∠ F–N–F	°	—	102.9(2)	102.4(1)	102.2		101.7(2)	101.0(3)	—

Data source: [99]

See also [100]. This document contains a data set of geometric parameters for *N,N*-difluoromethanamine (methyldifluoroamine).

3.3.9.2 Molecular Structure of Cyclic Difluoroamino Compounds

The structures of cyclic compounds containing geminal-difluoroamino groups were examined by XRD [101]. As an example of the structure of molecules containing geminal-difluoroamine groups, the crystal parameters of 1,1,4,4-tetrakis(difluoroamino)cyclohexane are listed here: monoclinic, *P*₂1/*n*, *a* = 6.277(1) Å,

$b = 10.502(2) \text{ \AA}$, $c = 7.910(1) \text{ \AA}$, $\beta = 99.50(1)^\circ$. The pyramidal difluoroamino group sometimes displays extensive torsional disorder in crystals, but in some structures, the geminal $-\text{NF}_2$ groups are primarily ordered owing to interactions with their steric environments. There are increases in the thermal parameters of the fluorine atoms indicating libration in some cases, where there are fewer steric demands in the NF_2 environment. The conformation adopted by each NF_2 group can be explained in terms of minimization of non-bonded $\text{F}\cdots\text{H}$ and $\text{F}\cdots\text{F}$ contacts. All NF_2 groups are non-planar and show unusual metrical parameters compared to amines containing no fluorine substituents. The interior $\text{F}-\text{N}-\text{F}$ and $\text{C}-\text{N}-\text{F}$ angles are very small, indicating a high degree of pyramidalization.

The IR spectrum of perfluoro-1,3,5-triazacyclohexane $(\text{CF}_2\text{NF})_3$ in the region $300\text{--}3000 \text{ cm}^{-1}$ was interpreted in terms of a structure with C_{3v} symmetry (the ring in chair form) in which the N-fluorines are equatorial [102].

DFT calculations were performed to predict the enthalpies of formation for three eight-membered ring compounds and four six-membered ring compounds via designed isodesmic reactions [103]. In the isodesmic reactions designed for the computation of enthalpies of formation, $(\text{CH}_3\text{CH}_2)_2\text{NNO}_2$ and piperidine were chosen as reference compounds. The enthalpies of formation for $-\text{NO}_2$ substituted derivations were larger than those of $-\text{NF}_2$ substituent groups. Thermal stabilities were evaluated by looking at bond dissociation energies. As a whole, the homolysis of $\text{C}-\text{NF}_2$ or $\text{C}-\text{NO}_2$ bonds is the main step for bond dissociation of these compounds. The detonation properties of seven compounds were evaluated using the Kamlet-Jacobs equation based on the calculated densities and enthalpies of formation. It was found that properties of 3,3,7,7-tetrakis(difluoroamino)octahydro-1,5-dinitro-1,5-diazocine (HNFX) and 3,3,5,5-tetrakis(difluoroamino)-1-nitro piperidine, with a predicted density of ca. 2.0 g/cm^3 , a detonation velocity of approximately 9.9 km/s , and a detonation pressure of 47 GPa are larger than those of HMX. The detonation data of 1,3,3,5,7,7-hexanitro-1,5-diazacyclooctane and 3,3-bis(difluoroamino)-7,7-dinitro-1-nitro piperidine showed that they would meet the requirements for HEDMs. See also [104]

3.4 Chemical Properties of Difluoroamino Compounds

3.4.1 Reactions of Difluoroamino Compounds

tert-Butyl-*N,N*-difluoroamine reacted rapidly with *n*-butyllithium, and the product was *n*-octane, with traces of azo-*tert*-butane [105]. A similar reaction of triphenylmethyl-*N,N*-difluoroamine with *n*-butyllithium gave biphenyl. In a reaction of *tert*-butyl-*N,N*-difluoroamine with concentrated nitric acid, the amine might be protonated but then decomposed into NO_2 and CO_2 .

Tris(difluoroamino)fluoromethane resists hydrolytic attack by dilute aqueous alkaline or acidic media at room temperature [29].

Hypergolic ignition of liquid difluoroamino compounds of the general structure $RR^1R^2CNF_2$, for instance 1,2-IBA, can be accomplished by contact with Lewis acids such as $AlCl_3$, $SbCl_5$, $TiCl_4$, or $GaCl_3$ [106]. Hypergolic ignition at sea level pressure occurred in 10–15 ms; at 0.69, 2.4, or 4.1 MPa (100, 350, or 600 psi) the ignition was instantaneous.

Generally difluoroamino compounds react with dehydrofluorinating agents (Et_3N , pyridine, KOH) that remove HF from molecules. Heating difluoroamino compounds like $R_2C(NF_2)CH_2NF_2$ with excess amines gave nitriles $R_2C(NF_2)CN$, with the amine forming its HF salt [107]. In all instances where HF was lost, the primary act was elimination of a proton from one of the C atoms bound to the NF_2 group. Diazomethane is a dehydrofluorinating agent where the carbanion intermediate is rapidly stabilized by elimination of F^- . Compounds with $-NF_2$ groups may be regarded as forms of amphoteric substances. The following compounds were examined (Table 13).

Table 13: Physical properties of difluoroamino compounds.

Compound	Melting point		Boiling point		Density	Refractive index
	K	°C	K	°C		
$MeCH(NF_2)CH_2NF_2$			355	82	1.265	1.3452
$Me_2C(NF_2)CH_2NF_2$			370	97	1.202	1.3598
<i>iso</i> - $PrCMe(NF_2)CH_2NF_2$			321 K at 2.67 kPa	48 °C at 20 mm Hg	1.178	1.3906
$Me_2C(NF_2)CMe_2NF_2$	365	92				

1,2-DP can be prepared in 98% yield by heating a 1:1 mixture of $MeCH=CH_2$ and N_2F_4 for 30 min at 408 K and can then be used for a study of dehydrofluorination reactions. Arrhenius factors in the dehydrofluorination of chemically activated 1,2-DP were calculated, giving a pre-exponential factor of $10^{13.1} s^{-1}$ and an activation energy of 159 kJ/mol (38 kcal/mol) [108]. *tert*-Butyldifluoroamine can form *N*-isopropylidene-*N*-fluoro-*N*-methylammonium ions [109].

3.4.2 Thermal Stability and Decomposition of Difluoroamino Compounds

3.4.2.1 Thermal Stability and Decomposition of Linear Difluoroamino Compounds

Thermal sensitivity was measured for a variety of C_3 – C_8 bis(difluoroamino) compounds. Vicinally and geminally substituted NF_2 compounds could be categorized into separate classes [110]. For example, 1,2,4,5-tetrakis(difluoroamino)pentane initiated 180 °C higher than the corresponding 2,2,4,4-isomer. Geminal NF_2 compounds with the substituents on an end carbon appear to fall in a different sensitivity class than compounds with the NF_2 groups on an internal carbon. Plotting the log of the ignition delay time versus $1/T$ allowed the derivation of activation energies. The most

sensitive compounds were the fluorinated biguanides and tris(difluoroamino)methyl ethers. A PFG explosion took place after a hypodermic needle tubing had been filled with the sample. A sample of $F_2NC(=NF)-NF-C(=NF)NF_2$, exploded while the container was being opened. Whether this sensitivity is the result of impurities or is inherent in the structure is not known.

The decomposition of 2-tris(difluoroamino)methoxyethylammonium perchlorate, an ionic solid salt, code name INFO-635P, in various forms was studied under widely different conditions ranging from aqueous and non-aqueous solutions and aqueous acid to the pure solid state [111]. Decomposition of the α -form of INFO-635P was rapid at room temperature and took place as a unimolecular reaction. The free amine from which the perchlorate salt was derived was unstable, and detonation of the salt in the solid state occurred almost immediately as soon as anhydrous ammonia gas was admitted. The tris- group of INFO-635P in acid decomposed at 373 K (100 °C) by homolytic rupture into free radicals, and the final products were analyzed by GC, IR, and NMR. In general, the gaseous product distribution from solid-phase decomposition was similar to that in acid solution. In the same report, the kinetics of decomposition of tetrakis(difluoroamino)methane (Compound Delta) in the gas phase was found to be very complex. The stoichiometry of the complete decomposition of Compound Delta apparently followed the equation

At the high end of the temperature range studied, 413–463 K (140–190 °C), the dominant reaction was homogeneous gas phase and first order in Compound Delta. A second competing mechanism became more dominant at the intermediate temperatures, where no distinct first-order rate was observed. The decomposition reaction at these lower temperatures was homogeneous, and possibly a reaction of 3/2 order.

Tris(difluoroamino)fluoromethane appeared to be thermally stable at temperatures below 473 K (200 °C). Differential thermal analysis in a sealed Monel cup revealed a slow exotherm beginning at 523 K (250 °C) with inflections at about 543 and 551 K (270 and 278 °C) [29]. The decomposition products were mainly carbon tetrafluoride, nitrogen trifluoride, and nitrogen.

A 193-page summary of the sensitivity and stability of NF compounds included some thermal stability data on 389 compounds assembled from 292 references, but unfortunately it did not include a summary of fundamental physical properties, which would have been available from the same sources [112].

The decomposition of 2,3-bis(*N,N*-difluoroamino)butane leads to a loss of two HF and the formation of 2,3-bis(*N*-fluoroimino)butane [113]. The decomposition of alkyl difluoroamino compounds at very low pressures (10^{-3} mm Hg) and high temperatures (1273 K = 1000 °C) was examined with only minor contributions from wall-catalyzed

decomposition and from chain processes. The initial step is the scission of the C—N bond. In the case of compounds containing two —NF₂ groups, migration of fluorine from nitrogen to carbon in the initially formed difluoroamino alkyl free radical takes place to a large extent. The heat release during decomposition is on the order of 160 kJ/mol (40 kcal/mol).

Alkyldifluoroamino compounds undergo rapid base-catalyzed dehydrofluorination leading to *N*-fluoroketimines, aldimines, or nitriles. The kinetics of dehydrofluorination of several mono-, bis-, and tris(*N,N*-difluoroamino) alkanes were measured in 3:7 diglyme-water dilution at 323 and 348 K (50° and 75 °C) [114]. The rates of these imine-forming reactions were relatively insensitive to the inductive and conjugative effects of substituents in the alkyl group. The stereoselectivity of the dehydrofluorination seems to reflect the steric requirements of the alkyl group. The elimination appears to be a concerted process in which the degree of N—F bond breaking is not only quite extensive but also nearly equal to the degree of C—H bond breaking in the transition state.

The pyrolyses of 1,2- and 2,2-DP were carried out at 923 and 1023 K (650 and 750 °C), respectively, and at 0.13 to 1.3 Pa (10⁻³ to 10⁻² mm Hg) [115]. The major reaction of 1,2 isomer was stepwise loss of both NF₂ groups to yield propylene, this process being the reverse of the addition of N₂F₄ to olefins. The 2,2 isomer decomposed completely by initial C—N scission, followed by both **(1)** migration of fluorine from nitrogen to carbon with subsequent fragmentation, yielding both the *syn* and *anti* isomers of CH₃C(=NF)F, and **(2)** loss of fluorine to yield (CH₃)₂C=NF. 1,1-DP, pyrolyzed at 923 K (650 °C), underwent C—N scission followed by fluorine migration to yield both the *syn* and *anti* isomers of HC(NF)F.

The thermal decomposition of ethyl difluoroamine C₂H₅NF₂ at 573–735 K (300–462 °C) was measured using static and flow methods [116]. The principal organic products were ethylene and acetonitrile. The reaction appeared to follow a molecular rather than a chain mechanism. The reaction was first order according to the rate expression

$$k = 10^{11} \exp(-38000/RT) \text{ s}^{-1}$$

The homogeneous thermal decomposition of gaseous tris(difluoroamino)fluoromethane FC(NF₂)₃ in the temperature range 498–523 K (225–250 °C) resulted in the formation of N₂, CF₄, and NF₃ in 1:1:1 molar ratio upon completion of the reaction [117]. The time-resolved growth and decay profile of difluoroaminotrifluoromethane and bis(difluoroamino)difluoromethane indicated that these compounds are intermediates. At an initial pressure of 13.33 kPa (100 mm Hg), the first-order rate constant would fit the Arrhenius equation

$$k = 1.36 \times 10^{15} \exp(-45800/RT) \text{ s}^{-1}$$

The gas-phase thermal decomposition kinetics of tris(difluoroamino)methyl chloride, (NF₂)₃C—Cl, tris(difluoroamino)methylamine, (NF₂)₃C—NH₂, tris(difluoroamino)-

methyl methyl ether, and $(\text{NF}_2)_3\text{C}-\text{O}-\text{CH}_3$ were measured in static reactors over the temperature range 457–503 K (184–230 °C) [118]. The reactions in each case were first order with activation energies of 151, 124, and 151 kJ/mol (36.1, 29.6, and 36.2 kcal/mol), respectively. A correlation was found between the order of stability and electronegativity of the group attached to the trisdifluoroamino functionality. The rate-determining step may be the homolysis of the C–N bond, similar to what happens in nitro compounds.

The abundance of positive ions in the mass spectra of three DPs (1,2-DP, 2,2-DP, and 2,3-DP) was measured to give an indication of the weakest links in the molecules [119]. The most abundant ions observed were the methylene fluoroimmonium ion $(\text{H}_2\text{C}=\text{NF})^+$ from the 1,2-DP and 1,3-DP and hydrocarbon-type ions from the 2,2-DP. The identities of the ions were verified by exact mass measurements. Mechanisms were postulated to account for the observed fragmentation patterns. Some of the observed ionization products originate via rearrangement reactions, possibly having a ring-like intermediate configuration. The ions seen in greatest abundance were those that proceeded through the minimal path for the overall ionic reaction process. Appearance potentials were measured for the more abundant ions formed from the three isomeric DPs studied.

The kinetics of thermal decomposition in the liquid state of 15 difluoroamino compounds with NF_2 groups at primary, secondary, and tertiary carbon atoms were investigated [120]. Activation energies (E_{act}) for all of these compounds were in the range 100–120 kJ/mol. The reaction rate did not depend on the electronic effects of the α -substituents and decreased only in the case of steric shielding of the NF_2 group. Based on the results obtained, a mechanism for liquid-phase decomposition was suggested that involved heterolysis of the N–F bonds.

The compounds $\text{RC}(\text{NO}_2)_2\text{NF}_2$ differed little from their nitro analogs, $\text{RC}(\text{NO}_2)_3$, in stability. They decomposed in the gas and liquid phases at identical rates and the decomposition was controlled by cleavage of a C– NO_2 bond [121]. For $\text{R} = \text{NO}_2$, F, and Me, the Arrhenius parameters E_{a} (kJ/mol) and $\log(A/\text{s})$ were as follows: 161.3 and 16.00; 180.2 and 16.20; 168.4 and 16.00, respectively. The facts that these decomposition reactions obeyed first-order kinetics and the rate constants did not depend on p_0 , S/V , or inhibitors and that the rates of decomposition in the gas and liquid states were similar implied that the decomposition was a homolytic monomolecular reaction. The magnitude of the pre-exponential factors agreed with a mechanism that involved dissociation of the molecule into two large moieties, i.e., cleavage of a C– NO_2 or C– NF_2 bond.

It has been shown that the decomposition of $\text{C}(\text{NF}_2)_4$, $\text{FC}(\text{NF}_2)_3$, and $\text{F}_2\text{C}(\text{NF}_2)_2$ starts with the cleavage of the C–N bond. The composition of gaseous products of 1,2- and 2,2-DP thermal decomposition also indicated that C–N bond cleavage took place first. Three types of difluoroamines were included in a study on NF_2 compound thermal decomposition: *gem*-bis(difluoroamino) compounds, compounds with solitary NF_2 groups, and α -polynitro(difluoroamino)alkanes with the aim of

determining the influence of molecular structure and substance aggregate state on decomposition parameters [122]. Reaction kinetics was studied under static conditions by a manometric method. The initial sample pressure p_0 varied from 20 to 150 Torr, and the S/V ratio of the vessel changed from 0.6 to 20 cm⁻¹. The decomposition of PhCH(NF₂)₂ vapors at $p_0 > 20$ Torr and S/V > 0.6 cm⁻¹ occurred on the surface and followed a different mechanism. The liquid-phase decomposition of some compounds proceeded with self-acceleration. The degree of the latter depended on the pressure of gaseous products (venting or non-venting) and decreased with increasing temperature. A comparison of difluoroamines and polynitroalkanes showed that the bond dissociation energy D(C–N) in difluoroamines was 12–16 kJ/mol higher than that in similarly structured nitroalkanes. The decomposition of α -(difluoroamino)polynitroalkanes occurred via cleavage of the C–NO₂ bond rather than the C–NF₂ bond. The kinetic parameters of thermal decomposition of α -(difluoroamino)polynitroalkanes and their nitro analogs are listed in Table 14.

Table 14: Kinetic parameters of thermal decomposition of α -(difluoroamino)polynitroalkanes and their nitro analogs.

Compound	State	Temperature		E_{act} kJ/mol	log(A/s)	k s ⁻¹ at 100 °C
		K	°C

Data source: [122]

DFT calculations have shown that the elimination of HF from H₃C–NF₂ is thermodynamically favored, $\Delta G(298.15 \text{ K}) = -121 \text{ kJ/mol}$ (-29 kcal/mol), but has a relatively high activation barrier, $\Delta G = 159 \text{ kJ/mol}$ (38 kcal/mol) [123]. The N–F dissociation energy, $\Delta E \text{ N–F}$, was found to be 289 kJ/mol (69 kcal/mol). The introduction of a nitro group, giving H₂C(NO₂)NF₂, produced only small changes in these values: $\Delta G(298.15 \text{ K}) = -117 \text{ kJ/mol}$ (-28 kcal/mol); barrier of $\Delta G = 151 \text{ kJ/mol}$ (36 kcal/mol); $\Delta E \text{ N–F} = 276 \text{ kJ/mol}$ (66 kcal/mol). Replacement of all alpha hydrogens by methyl groups increased the N–F dissociation energies slightly ($< 8.4 \text{ kJ/mol} = < 2 \text{ kcal/mol}$). These substituent effects can be interpreted in terms of geminal interactions.

The thermal stability of TVOPA in the Differential Thermal Analysis (DTA) showed an exothermic peak at 538 K (265 °C). For comparison, GTN (NG) showed an exothermic peak at 469 K (196 °C). Other sources reported a start of decomposition at 374 K (111 °C) and a major exotherm at 547 K (274 °C).

The stability and compatibility of the plasticizers TVOPA, 1,2,3-tris[1,2-bis(difluoroamino)]ethoxy propane, and P-722, 2,3-bis(difluoroamino)propyl-2,2-dinitropropyl carbonate were investigated and compared [124]. A study of their stability and compatibility with the oxidizers hydroxylammonium perchlorate (HAP) and ammonium perchlorate (AP), the fuel AlH_3 , and an ethyl acrylate-acrylic acid copolymer showed that neat P-722 did not yield appreciable quantities of gaseous decomposition products at ambient temperature or 313 K (40 °C) for test durations up to 340 d. At 328 K (55 °C), only small quantities of gases were formed over the same time period. Samples stored at 343 K (70 °C) for approximately 1 year (340 d) yielded a total gas volume of about 36 mL/g of P-722; the gases were primarily CO , CO_2 , and N_2O with small amounts of H_2 and N_2 . Little gas evolution was observed from TVOPA after 310 d at 343 K (70 °C). Mixtures of P-722 and AP showed very small quantities of gaseous products at all four temperatures after 326 d. The same result was observed for P-722/HAP mixtures at 298 and 313 K (25 and 40 °C) over the same time interval. At 328 K (55 °C), the P-722/HAP mixtures evolved a total volume of gaseous products equal to 37 mL/g. In general, TVOPA and P-722 exhibited comparable stabilities after 300 d at 298, 313, or 328 K (25, 40, or 55 °C). At 343 K (70 °C), TVOPA appeared to be slightly more stable than P-722. Both materials had adequate thermal stability for use in a propellant system. Compatibilities with the oxidizers HAP and AP are very similar. At 298, 313, or 328 K (25, 40, or 55 °C), P-722 appeared to be slightly more compatible with the two oxidizers than TVOPA, while at 343 K (70 °C) TVOPA was better.

The gas-phase thermal decomposition of tetrakis(difluoroamino)methane, $\text{C}(\text{NF}_2)_4$, tris(difluoroamino)fluoromethane, $\text{FC}(\text{NF}_2)_3$, and bis(difluoroamino)difluoromethane, $\text{F}_2\text{C}(\text{NF}_2)_2$, in an inert carrier gas was investigated over the temperature range 463–733 K (190–460 °C) in stirred flow, tubular flow, and static reactors [125]. The reactions are first-order, non-chain processes with C–N bond rupture as the rate-determining step in each case. The rate constants are given by the following Arrhenius expressions:

$$\begin{array}{ll} \text{C}(\text{NF}_2)_4 & k = 10^{16.14} \exp(-40400/RT) \text{s}^{-1} \\ \text{FC}(\text{NF}_2)_3 & k = 10^{16.45} \exp(-48300/RT) \text{s}^{-1} \\ \text{F}_2\text{C}(\text{NF}_2)_2 & k = 10^{15.75} \exp(-53600/RT) \text{s}^{-1} \end{array}$$

The compound with the lowest activation energy was the thermally least stable. The rate parameters obtained were quite analogous to the polynitro compounds, again suggesting that the rate-determining step involves the simple cleavage of a C–N bond.

A study of the kinetics of thermal decomposition of difluoroamino compounds was conducted with the goal of obtaining leads to methods of reducing their detonation sensitivity [126]. The investigation of the pyrolysis of tetrakis(difluoroamino)-methane (Compound T or Compound Delta) was extended up to 800 K (528 °C). For this purpose, a tubular 2.4-mL-volume reactor was constructed from 1/8-in. copper tubing. This small reactor allowed for very short residence times (7 to 190 ms) and, therefore, much higher temperatures. At higher temperatures, the initial products were almost exclusively PFG, NF_3 , and N_2F_4 . It was definitively established that PFG is a direct intermediate in the decomposition of Compound T. The pyrolysis of Compound T occurs via the cleavage of a C—N bond:

followed by the first or both of the following processes:

The pyrolysis of PFG was then studied in the same reactor. The thermal stabilities of Compounds T, R, and H studied over the temperature range of 463 to 733 K (190 to 460 °C) were found to decrease markedly in the order $\text{H} > \text{R} > \text{T}$. This is precisely the order of increasing detonation sensitivity for this series of compounds.

The thermal decomposition of

INFO-635P	2-Tris (difluoroamino) methoxy ethylammonium perchlorate
PBEP	Poly [1,2-bis(difluoroamino)-2,3-epoxy propane]
PFABD	Poly [1,4-bis[tris(difluoroamino) methoxy butene oxide-2,3]

was investigated by a mass spectral thermal analysis (MTA) method using a time-of-flight mass spectrometer [127, 128]. In this method, microgram quantities of the materials were deposited on a small platinum ribbon that was heated ohmically by battery current or by condenser discharge. Using battery current, a linear heating rate was obtained that could be varied from 10 to 1000 °C/s (dynamic heating). With the

condenser discharge, the sample temperature was brought instantaneously (10 ms) to a predetermined temperature that was maintained for 50 ms (isothermal heating). The decomposition of these compounds was accelerated by impurities, and subsequent work served to determine which, if any, of the purification procedures produced desirable gains in propellant thermal stability and shelf life [129].

3.4.2.2 Thermal Stability and Decomposition of Cyclic Difluoroamino Compounds

The decomposition reactions of $-\text{NF}_2$ compounds discussed thus far were for open-chain compounds. The following compounds contain a ring to which F atoms or $-\text{NF}_2$ groups have been attached.

Ammonium, 1,5-diamino-4-methyl-tetrazolium, and 4-amino-1-methyl-triazolium salts of 5-difluoroaminodifluoromethyl-tetrazolate were prepared by metathesis reactions of silver 5-difluoroaminodifluoromethyl-tetrazolate and the corresponding iodides [130]. All salts were thermally stable to $\sim 423\text{ K}$ ($\sim 150^\circ\text{C}$). The ammonium salt had a density of 1.88 g/cm^3 . The standard heat of formation of ammonium 5-difluoroaminodifluoromethyl-tetrazolate was calculated to be -53.13 kcal/mol using the CBS-4 method. 1,5-Diamino-4-methyl-tetrazolium 5-difluoroaminodifluoromethyl-tetrazolate had a density of 1.69 g/cm^3 and an enthalpy of formation of $+52.56\text{ kJ/mol}$.

The following alicyclic and heterocyclic difluoroamino and nitro compounds may not necessarily be suitable as rocket propellants, but they have served as model compounds to study the effect of molecular structure on thermal stability.

The decomposition rates and product distributions of a number of nitro- and difluoroamino-substituted six-membered rings were compared: nitrocyclohexane (I); 1,1-dinitro-cyclohexane (II); 1,1,4,4-tetranitrocyclohexane (III); 1,1,4,4-tetrakis(difluoroamino)cyclohexane (IV); 1,4-dinitropiperazine (V); 1,4,4-trinitropiperidine (VI); and 4,4-bis(difluoroamino)-1-nitropiperidine (VII). The following order was suggested for decreasing susceptibility to decomposition: $\text{N}-\text{NO}_2 > \text{C}-(\text{NO}_2)_2 > \text{C}-(\text{NF}_2)_2$ [131]. The difference in bond energies among the compounds was small. Geminal bis(difluoroamino) compounds appeared to be somewhat more stable than the corresponding *gem*-dinitro compounds, although they released more heat during decomposition. The decomposition of *gem*-bis(difluoroamino) and *gem*-dinitro compounds exhibited some similarities. Both experienced loss of one geminal NX_2 group followed by the rearrangement of the remaining NX_2 . Where X was oxygen, loss of the initial nitro by homolysis was favored; rearrangement of the remaining nitro followed by the homolysis of NO resulted in a C—O bond. Where X was fluorine, the initial difluoroamino may have been lost as HNF_2 . The remaining difluoroamino reacted by losing fluorine, leaving CNF, or losing HNF, resulting in C—F.

The decomposition of 1,1,4,4-tetrakis(difluoroamino)cyclohexane and 3,3,7,7-tetrakis(difluoroamino)octahydro-1,5-dinitro-1,5-diazocine (HNFX) under the conditions of electron ionization mass spectrometry appeared to parallel the thermal decomposition of nitramines where $\text{N}-\text{NO}_2$ cleavage is often the first step [132].

3.4.3 Strand Burning of Difluoroamino Compounds

Very little is known about the strand burning rates of difluoroamino compounds. They appear to be so sensitive that in many instances a plain burning quickly transitions to a detonation. Strand burning of difluoroamino compounds will be discussed again in *Encyclopedia of Monopropellants*.

Normally, the addition of metal salts increases the linear burning rates of monopropellants, but here the opposite appears to be the case. FeCl_3 (preferred), ZnCl_2 , SnCl_2 , and $\text{Pb}(\text{OAc})_2$ were proposed to reduce the high burning rate and danger of explosions attendant upon use of difluoroamino compounds as propellants and, at the same time, increase injection port critical quench diameters to facilitate injection of fuel into rocket motor combustion chambers without flashbacks [133]. Thus, 1 mass-% of FeCl_3 was added to 1,2-IBA, stirred for 1 min at ambient temperature, and excess FeCl_3 was removed by filtration. In 0.5-mm-diameter burning tubes at 0.69 MPa (100 psi), the desensitized mixture thus prepared burned at 0.6 cm/s, while the pure difluoroamino compound burned at 1.3 cm/s. At 6.2 MPa (900 psi), the pure material always detonated, while the FeCl_3 -containing solution burned progressively (no burning rate given).

3.4.4 Analysis of Difluoroamino Compounds

Fluorination of PFG or guanylurea results in the formation of a medley of difluoroamino compounds that are difficult to separate, unless one uses preparative liquid column chromatography, which avoids the accumulation of detonable fractions that might otherwise form during preparative GC or fractionated condensation [134].

Linde 5A molecular sieves will selectively adsorb bis(difluoroamino)difluoromethane while quantitatively excluding the slightly larger tris(difluoroamino)fluoromethane [31].

3.5 Safety Properties of Difluoroamino Compounds

3.5.1 Explosion Sensitivity of Difluoroamino Compounds

Difluoroamino compounds can be divided roughly into three classes based on their sensitivity: (1) relatively insensitive compounds, substituted with a low ratio of NF_2 groups to carbon; (2) compounds with substitution at a ratio of up to one NF_2 group per carbon, possessing high energy, and exhibiting sensitivity characteristics that are about the same as those of nitroglycerin or HMX; and (3) ultrasensitive compounds, of very high energy, which are more sensitive than nitroglycerin and HMX and are difficult to desensitize [135]. In the first class are long-chain alkanes, mono- and bis-substituted with NF_2 groups (exceptions are the geminally substituted compounds). In the second class are bis(difluoroamino) compounds such as the DPs, tris(difluoroamino)alkane compounds at a ratio of one NF_2 to one methylene

group and substituted in the 1,2,3-, 1,1,2- or 2,2 positions, and compounds with more than three NF_2 groups. The third class consists primarily of tris(difluoroamino) compounds. The sensitivity characteristics of the various classes of NF compounds can be correlated with the number and position of the NF_2 groups on the carbon chain, and some types of substitution are particularly sensitive to certain methods of energy input, e.g., to spark initiation or to friction. The general sensitivity of a compound is established by the NF_2 substitution and is usually not intensified by the effect of other oxidizing groups such as nitro or nitrate. Vicinal substituted compounds at a ratio of about two NF_2 groups to three carbon atoms are in the nitroglycerin sensitivity range. Geminal NF_2 groups impart more sensitivity to a compound than do vicinal groups, particularly when the geminal group is terminal, as in the 1,1 position. Desensitization of geminal compounds by increasing the carbon content is ineffective. Generally, energetic geminal compounds are in the nitroglycerin sensitivity range and appear to be especially susceptible to spark and shock initiation. Separation of NF_2 groups by one or more CH_2 groups appears to make the compounds less sensitive, but the magnitude of improvement is not large.

3.5.1.1 Explosion Limits of Difluoroamino Compounds

The explosion limits of difluoroamino compound vapors in sturdy vessels made from various construction materials and in dilution with inert gases were determined as a function of the mode of initiation, total pressure, partial pressure, and composition [136]. The explosion products were analyzed, and an attempt was made to explain the chain of reactions that led to their formation. A long series of progress reports documented this work, which lasted several years from 1963 to 1969. It is unclear what compound was used for most of the tests; 1,2-DP was initially supposed to be used, and it was examined exhaustively for its explosion limits. Presumably it was intended to be used as a monopropellant.

Vapors of bis(difluoroamino)propanes (DP) $\text{C}_3\text{H}_6(\text{NF}_2)_2$ and bis(difluoroamino)butanes (DB) $\text{C}_4\text{H}_7(\text{NF}_2)_2$ were exploded either thermally by raising the temperature or by injecting a small amount of fluorine. For the thermally induced explosion the experiments yielded explosion limits as functions of pressure p , temperature T , and vessel diameter d . Three DP isomers and three bis(difluoroamino)butane isomers were selected for this study. These compounds were sufficiently volatile at room temperature (25°C) for admission of the vapors to a reaction vessel at 4.0 to 5.3 kPa (30 to 40 mm Hg) for DP and 1,2-IBA (IBA), and at 2.7 to 4 kPa (20 to 30 mm Hg) for 1,2-DB and 2,3-DB. For the fluorine-induced explosion the experiments yielded explosion limits in terms of critical fluorine concentrations $F_{2\text{crit}}$. The data showed that the reaction is of the branched-chain type and that at the explosion limits the relation Rate of Chain Branching = Rate of Chain Breaking is applicable. Using this relation in conjunction with chemical analysis of the reaction products and auxiliary data from photochemical experiments, a series of reaction mechanisms was proposed. Abstraction of the first hydrogen gave a free radical $\cdot\text{C}_3\text{H}_5(\text{NF}_2)_2$. The decomposition of the free radical

$\cdot\text{C}_3\text{H}_5(\text{NF}_2)_2$ to yield $\text{NF} + \text{F}$ rather than NF_2 was interpreted in terms of a sequential activation of the F-atoms in the two NF_2 groups of the radical R. Each group loses one F atom in reactions with neighboring H atoms to form HF, so that the formation of the molecules HCN and C_2H_2 in the final break-up releases one radical NF and one F atom. This principle also applies to the ternary reaction $\text{F} + \text{DP} + \text{F}_2$, except that one NF_2 group is preserved because the F_2 molecule furnishes an F atom to serve as reaction partner to one of the H atoms in the carbon chain.

The go/no go results were graphed in terms of the product of pressure and vessel diameter versus reciprocal absolute temperature. The boundary between explosion and no explosion was a fairly sharp line curving upward. The activation energy for the unimolecular decomposition reaction of 1,2-DP was $\sim 105 \text{ kJ/mol}$ ($\sim 25 \text{ kcal/mol}$).

The existence of a critical fluorine concentration above which a DP-F_2 mixture explodes spontaneously even at low temperature was noted in attempts at preparing a 1,2-DP/ F_2 mixture at room temperature. For this purpose fluorine was gradually added in small increments to 1,2-DP vapor. No detectable reaction took place between F_2 and 1,2-DP vapor if the partial pressure of F_2 was less than about 200 Pa (1.5 mm Hg), whereas an increase of the F_2 pressure to 200 Pa (1.5 mm Hg) or more produced explosive reaction characterized by a clicking sound, a luminous flash, and a sharp pressure rise.

Initial pyrolysis data of gaseous 1,2-DP at 523–543 K (250–270 °C) appeared to obey half-order kinetics and were surface dependent [137]. Additional measurements of pyrolysis rates of 1,2-DP in the 300–350 °C range reinforced earlier evidence that the reaction was surface dependent [138]. Induction times could be correlated to explosion limit pressures.

Critical pressure limits for explosion at 633–663 K (360–390 °C) for pure 1,2-DP determined in a 1090-cm^3 bulb were found to be lower by a factor of about 3 than the values found in a 216-cm^3 bulb [139]. Helium dilution did not affect the limit at all, while nitric oxide addition lowered it sharply.

The explosion limits of 1,2-DP were compared to those of equimolar mixtures of propylene and tetrafluorohydrazine (reactants used in the preparation of 1,2-DP) [140]. Analyses of the gaseous products of the explosion of 1,2-DP showed nitrogen, hydrogen, carbon monoxide, hydrogen cyanide, acetylene, and silicon tetrafluoride to be among the products, but acetylene was not present among the products below the explosion limit [141].

Manometric measurements of the thermal decomposition of 2,2-DP in Pyrex vessels of differing surface-area-to-volume ratios in the temperature range 549–573 K (276–300 °C) indicated that the reaction is a homogeneous first-order reaction with an activation energy of about 159 kJ/mol (38 kcal/mol) [142]. Equimolar nitric oxide-2,2-DP mixtures exploded less readily than pure 2,2-DP.

The products of the explosive and non-explosive thermal decompositions of IBA were analyzed for HCN and C_2H_2 and products not condensable in liquid nitrogen [143]. The HCN yields for explosion were approximately 1 mol per mol IBA consumed;

for non-explosive decomposition the yields were much lower. An analytical method utilizing IR spectroscopy to determine the rate of thermal decomposition of 2,2-DP indicated that the reaction was homogeneous and first-order and had an activation energy of about 188 kJ/mol (45 kcal/mol). Butane homologs differed from the propane homologs by their high sensitivity to traces of fluorine, and it is therefore very probable that the occurrence of an accidental, premature reaction involved the generation of traces of fluorine by catalytic decomposition of IBA or DB at the vessel surface.

Drop weight sensitivity of 1,2-DP and IBA correlated very well with sensitivity, as indicated by thermal explosion limit measurements [144]. The thermal decomposition of 2,2-DB followed a first-order rate corresponding to

$$k = 10^{15.7} \exp(-46,500/RT) \text{ s}^{-1}$$

Data on the explosion limit of 1,2-DP were inconsistent with the concept of thermal explosion and required interpretation in terms of a branched-chain mechanism [145]. The chemical and kinetic evidence suggested a mechanism of the form

The initiation mechanism in drop weight tests can be interpreted in terms of heat transfer from adiabatically compressed gas bubbles in the sample volume to the explosive liquid. Data from the initiation of IBA using various gases in the sample volume can be correlated in terms of the temperature rise of the gas-liquid interface due to the impact of the drop weight.

Explosion limits of 1,2-DP and 2,2-DP were measured at pressures up to 26.7 kPa (200 mm Hg) by rapid immersion of a flask containing a measured liquid volume in a heated salt bath [146].

Explosion limits for 1,3-DP indicated that the chain branching step involved a unimolecular decomposition of the chain carrier $\text{F}_2\text{N}-\text{CH}_2-\dot{\text{C}}\text{H}-\text{CH}_2-\text{NF}_2$ [147]. In the absence of a low temperature limit, chain branching occurred in the gas phase and chain termination occurred at the surface only. Kinetic data indicated that 1,2-DP decomposed heterogeneously while 2,2-DP decomposed homogeneously [148]. For explosive conditions the volume ratio of 1,2-DP decomposition products was $\text{N}_2:\text{C}_2\text{H}_2:\text{HCN} = 2.5:1:1$ [149].

The key problem in the branched-chain explosion of difluoroamino propanes is the mechanism of deactivation of F atoms. This may occur either subsequently to the reaction $\text{F} + \text{DP} = \text{HF} + \text{R}$ by decomposition of the free radical R to yield inert NF_2 instead of $\text{NF} + \text{F}$, or competitively by the reaction $\text{F} + \text{DP} = \text{C}_3\text{H}_6\text{F}(\text{NF}_2) + \text{NF}_2$ while R in

the presence of F_2 at low temperature reacts to yield $RF + F$ and at high temperature decomposes to yield $NF + F$. Photochemical experiments with Cl_2 and F_2 at subcritical concentrations have confirmed the latter theory, pointing to a common branched-chain mechanism for the various DP isomers [150]. Comparison of the kinetic data for 1,3-DP with 1,2- and 2,2-DP showed that a primary carbon atom was much less susceptible to reaction $F + DP = C_3H_6F(NF_2) + NF_2$ than a secondary carbon atom.

The fluorine-induced explosions of C_4 difluoroamino compounds $(CH_3)_2C(NF_2)-CH_2(NF_2)$, $F_2N-CH_2-CH(NF_2)-CH_2-CH_3$, $CH_3-CH(NF_2)-CH(NF_2)-CH_3$ (code names IBA, 1,2-DB, and 2,3-DB, respectively) and the C_5 homolog $(CH_3)_2C(NF_2)-CH(NF_2)-CH_3$ (code name M-2,3-DB) were studied by admitting measured amounts of F_2 to the vapors of these compounds in a 200-cm³ Pyrex bulb at pressures of 1.07 kPa (8 mm Hg) or less [151]. Whereas very small amounts of F_2 were required to produce explosions with IBA, larger amounts of F_2 were required to produce explosions with 1,2-DB and 2,3-DB, and substantial amounts of F_2 were required to produce an observable luminous flash with M-2,3-DB. Samples of IBA and 1,3-DP were decomposed to completion with F_2 , and the decomposition products were analyzed by MS.

From the explosions of vapors of the three isomeric DPs, 1,2-DP, 1,3-DP, and 2,2-DP, and bis(difluoroamino)butanes in spherical glass vessels, either by heating or by addition of difluorine at 273–373 K (0–100°C), and from photochemical experiments and thermochemical and kinetic consideration of the data, the mechanisms of the reactions of DPs and bis(difluoroamino)butanes with difluorine were examined [152]. The vapor-phase reaction of DPs with F_2 below 100°C involved chain branching and breaking by reaction with $F^\bullet$ and $O^\bullet$ to form O_2F and then inert products. Differences among the 1,2, 1,3, and 2,2 isomers of DP were documented. Collisions between bis(difluoroamino)butanes and F_2 led to chain breakage by complex reactions, depending on the isomer structure. Data on the vapor-phase reaction of propyl isomers $C_3H_6(NF_2)_2$ with F_2 below 373 K (100°C) conform to the chain mechanism

with R being the free radical $\bullet C_3H_6(NF_2)_2$. These equations are not stoichiometrically balanced.

Over a period of several years, Stanford Research Institute (SRI International) has conducted an exhaustive series of investigations on the sensitivity fundamentals of difluoroamino compounds, as well as in comparison with nitro compounds. Much of the work was directed at determining the ability of energetic compounds to undergo low-

velocity detonations (LVDs). This has resulted in a flood of quarterly, semi-annual, and annual progress reports; only a few selected ones have been reviewed for this chapter on difluoroamino compounds, and the reader will need to dig through a stack of additional reports if more detailed information is needed. A 193-page summary of the sensitivity and stability of NF compounds included sensitivity data on 389 compounds, including Compound R, Compound T (= Compound Delta), and many others [112]. The information on sensitivity obtained during previous RNF_2 synthesis research programs had been primarily incidental (accidental) and uncorrelated, gathered by laboratories working independently of each other and each using different empirical tests, often modified from their “standardized” forms. Other sensitivity testing has been reported by laboratories engaged in development programs. Consequently, a large volume of sensitivity information is scattered throughout the technical literature. Data from sensitivity tests conducted on 400 NF compounds between 1960 and mid 1966 were compiled by SRI. The scope of the compilation included testing information from impact, friction, static, shock, and compression tests and from thermal stability measurements. The objective was to establish relationships between sensitivity, structure, and thermal decomposition mechanisms and kinetics. The physical properties of these compounds should have been documented at the same time, but that was not done.

The LVD wave propagation characteristics of 1,2-, 1,3-, 1,1-, and 2,2-DP, 1,2-bis(difluoroamino)2-methylpropane, 2,3-bis(difluoroamino)butane, 1,2,2-tris(difluoroamino)propane, and 2,3,3-tris(difluoroamino)butane were examined [153]. This was supposed to give a better understanding of the effect of vicinal and geminal difluoroamino groups on the stability of the molecules. See also [154, 155].

3.5.2 Drop Weight Impact Sensitivity of Difluoroamino Compounds

The drop weight impact sensitivities of several difluoroamino alkyl compounds are listed in Table 15. In some cases, the impact sensitivity of RDX as determined on the same apparatus was listed for comparison. These data came from different laboratories and may reflect the use of different machines, as indicated by the different units used. The least sensitive compound in this collection was *tert*-butyldifluoroamine; the most sensitive compound was PFG.

Completely fluorinated guanidine (PFG) is an extremely sensitive molecule and has contributed to several accidental explosions in the laboratory and pilot plants. Explosions can be initiated easily by shock, spark, or impact. Other guanidine derivatives have similar severe sensitivity characteristics.

An evaluation of $\text{C}(\text{NF}_2)_4$ (Compound T or Compound Δ) as a higher-performance replacement for $\text{FC}(\text{NF}_2)_3$ (Compound R) in formulated oxidizer mixtures was terminated because of the extremely unfavorable results obtained from shock sensitivity and detonation propagation experiments on mixtures containing Compound T [126]. Mixtures of Compound T with ClF_5 , N_2F_4 , and $\text{C}(\text{NO}_2)_4$ fared no better, but their vapor

Table 15: Drop weight impact sensitivities of difluoroamino alkyl compounds.

Compound formula	50% drop weight impact sensitivity
$(\text{H}_3\text{C})_3\text{CNF}_2$	39 kg in.; RDX = 10 kg in.
$\text{CH}_2(\text{NF}_2)_2$	0.1 kg cm
$\text{F}_2\text{NCH}_2\text{CH}_2\text{NF}_2$	11 kg in.; RDX = 20 kg in.
$\text{CH}_3\text{C}(\text{NF}_2)_2\text{CH}_3$	2.8 kg in.; RDX = 10 kg in.
$\text{CH}_3\text{CH}(\text{NF}_2)\text{CH}_2\text{NF}_2$	14 kg in.; RDX = 20 kg in.
$\text{F}_2\text{NCH}_2\text{CH}_2\text{CH}_2\text{NF}_2$	>170 cm/2 kg
$\text{F}_2\text{NCH}_2\text{C}(\text{CH}_3)(\text{NF}_2)\text{CH}_3$	5.7 kg cm
$[\text{H}_3\text{CCH}(\text{NF}_2)]_2$	32 kg in
$\text{H}_3\text{CC}(\text{NF}_2)_2\text{CH}_2\text{CH}_3$	4.0 kg in.
$\text{F}_2\text{NCH}_2\text{CH}(\text{NF}_2)_2$	1–5 kg in.
$\text{F}_2\text{NCH}_2\text{CH}(\text{NF}_2)_2\text{CH}_2\text{NF}_2$	7–18 kg cm
$\text{C}(\text{NF}_2)_4$	42 kg cm
$\text{FN}=\text{C}(\text{NF}_2)_2$	0.1 kg cm (!!!)

Data source: [112]

pressures were measured, and the theoretical performance with B_5H_9 and MMH was calculated anyway.

The drop weight impact sensitivity of $\text{C}_9\text{H}_{14}\text{F}_{12}\text{N}_4\text{O}_3$, $[\text{F}_2\text{NCH}_2\text{CH}(\text{NF}_2)\text{OCH}_2-]_2\text{CHOCH}(\text{NF}_2)\text{CH}_2\text{NF}_2$, and TVOPA liquid was measured in a Bureau of Mines machine [112]. Its impact sensitivity was greater than that of RDX and comparable to that of glycerol trinitrate (GTN), also called nitroglycerin (NG). Impact sensitivities of difluoroamino compounds in comparison with that of other energetic materials determined with the Picatinny drop weight tester are shown in Table 16.

Table 16: Drop weight impact sensitivities of difluoroamino compounds in comparison with other energetic materials.

Compound	Acronym	Calculated 50% point	
		cm	in.
Trimethylolethane trinitrate	TMETN	56	22.2
Glycerol trinitrate/ethylene glycol mix	GTN (NG)/EG (60/40)	30	11.7
Glycerol trinitrate	GTN (NG)	27	10.7
Triethylene glycol dinitrate	TEGDN	>96	>38

Note: Acronyms are identified in Table 18

3.5.2.1 Drop Weight Impact Sensitivity of Difluoroamino Compound Mixtures

Difluoroamino compounds derived from the reaction of tetrafluorohydrazine with alkenes with up to eight carbon atoms can be mixed with nitric acid to reduce their impact sensitivity [157]. A preferred example was HNO_3 at 0.5–0.6 times the stoichiometrically required amount of oxidizer mixed with IBA made from isobutylene and N_2F_4 . The IBA thus obtained had a vapor pressure of 12 mm Hg at 0 °C, 26 mm Hg at 15 °C, and 49 mm Hg at 28 °C. The atmospheric pressure b.p. was predicted to be 99 °C. These mixtures have reduced shock sensitivity compared to pure difluoroamino compounds. The drop weight sensitivity of pure IBA was $E_{50} = 6.9 \text{ kg}\cdot\text{cm}$, which is more sensitive than GTN, but the E50 mixture was 50 kg·cm. The lower homolog 1,2-bis(difluoroamino)propane had a vapor pressure of 21 mm Hg at 0 °C.

3.5.3 Friction Sensitivity of Difluoroamino Compounds

The friction sensitivity of TVOPA was positive at a 0.37 relative friction number at 750 rpm and negative at 2700 rpm but positive at 2800 rpm.

3.5.4 Card Gap Sensitivity of Difluoroamino Compounds

The card gap sensitivity of difluoroamino compounds (and that of many other energetic compounds) depends on the strength of confinement. In a series of tests, keeping the charge diameter constant, the effect of the ratio of wall thickness to charge diameter on the number of cards required to obtain the first negative test was measured.

The SRI Sensitivity Fundamentals program has existed for a very long time. During one period of this program, the card gap sensitivity of 1,2-DP and IBA had been measured [154]. 1,2-DP was so sensitive in the card gap test that it required a large number of Plexiglas cards before the shock wave was sufficiently attenuated and the first negative test was obtained. Therefore, additional LVD tests were conducted with IBA instead. In a 1.27-cm diameter, 10.2-cm-long charge of IBA with a wall thickness:diameter ratio of 0.2, the card gap value for all negative initiation was 18.5–21 cm Plexiglas. For 1,2-DP under the same condition it was 66–122 cm. For comparison, the card gap of ethyl nitrate was 3.1–3.8 cm. This means that the difluoroamino compounds were much more sensitive than the alkyl nitrate.

In another card gap test, the 50% point of TVOPA was at a stack of cards 27 mm (1.05 in.) thick. For comparison, the card gap sensitivity of GTN was 23 mm (0.9 in.).

In a series of tests to study LVD, 1,2-DP was tested in lead and steel tubes in comparison with ethyl nitrate and a nitromethane (NM)/TNM mixture. The results differed depending on whether a witness plate was at the end of the sample or not. The results are shown in Table 17.

Because only a limited amount of difluoroamino compounds was available to test card gap sensitivity, the standard card gap test (3.6 cm ID $\times$ 15.2 cm length acceptor with a 9.5-mm-thick witness plate geometry) had to be scaled down to an acceptor geometry of 0.9-cm diameter $\times$ 6.3-cm length in a Schedule 40 water pipe [156]. A small-

Table 17: LVD gap sensitivities of 1,2-DP in comparison with ethyl nitrate and a NM/TNM mixture.

Compound	Confinement, steel tubes		LVD gap sensitivity, cm of Plexiglas	
	ID, cm	Wall thickness, cm	Witness plate	No witness plate
1,2-DP	12.7	0.63	>91–<126	<61 (camera)
Ethyl nitrate	12.7	0.23	>2.54–<5.4	>3.8–<5.1 (probe)
NM/TNM (18.7/81.3 mass-%)	12.7	0.63	>8.9–<10.2	11.0 (probe)

Data source: [158]

scale test was used in which only the acceptor and witness plate were reduced in size and the donor and barrier remained the same. The premise was that, with a given gap and explosive train, the card gap value would not be strongly dependent upon the acceptor diameter. The acceptor configuration was that of a sample contained in a 6.3-cm (2.5-in.) length of nominal 0.9-cm (3/8-in.) ID Schedule 40 steel water pipe; the witness plate was a 7.6 × 7.6-cm (3 × 3-in.) sheet of 3.2-mm (1/8-in.) thick mild steel. A series of substances was tested in each configuration and a comparison was made. The two tests correlated well, and the small-scale test gave card gap values 2–2.5 mm

Table 18: Small-scale card gap sensitivity values of difluoroamino compounds in comparison with other energetic materials.

Compound	Acronym	Formula	Gap width	
			mm	in.
Trimethylolethane trinitrate	TMETN	$(\text{O}_2\text{NOCH}_2)_3\text{CCH}_3$	7.6	0.30
Glycerol trinitrate/ethylene glycol mix	NG/EG (3/1)		13	0.51
Glycerol trinitrate	GTN (NG)	$\text{O}_2\text{NOCH}_2\text{CH}(\text{ONO}_2)\text{CH}_2\text{ONO}_2$	23	0.91
1,2,3-Tris[1,2-bis(difluoroamino)]ethoxy propane	TVOPA	$[\text{F}_2\text{NCH}_2\text{CH}(\text{NF}_2)\text{OCH}_2]_2\text{CHOCH}(\text{NF}_2)\text{CH}_2\text{NF}_2$	27	1.05
1,2,2,5,9,9,10-Octakis(difluoroamino)-4,7-dioxadecane	OPE	$(\text{F}_2\text{NCH}_2\text{CHNF}_2\text{CHNF}_2\text{OCHNF}_2)_2$	26	1.03
1,2,3,5,6,7-Hexakis(difluoroamino)-4-oxaheptane	HPE	$(\text{F}_2\text{NCH}_2\text{CHNF}_2\text{CHNF}_2)_2\text{O}$	30	1.19
2,3-Bis(difluoroamino)-propyl acrylate	NFPA (monomer)	$\text{H}_2\text{C}=\text{CHCOOCH}_2\text{CHNF}_2\text{CH}_2\text{NF}_2$	31	1.21

Data source: [156]

(0.08 to 0.10 in.) higher, on average, than the large-scale test. Table 18 gives small-scale card gap sensitivity values for TVOPA, NFPA, and several other energetic liquids. It is assumed that the gap listed is the gap where the sample failed to detonate (negative test) and not the gap at the last positive test.

The failure diameter of TVOPA and NFPA in a Schedule 40 steel pipe with $L/D > 4$ was <0.48 in. In the DTA, the exotherm of TVOPA maxed out at 538 K (265 °C), compared to 469 K (196 °C) for GTN (NG).

3.5.5 Adiabatic Compression Sensitivity of Difluoroamino Compounds

Several difluoroamino compounds were tested for adiabatic compression sensitivity in a U-tube apparatus in comparison with ethyl nitrate and isopropyl nitrate [126]. The 50% probability for positive results in these sensitivity tests of Compound R under its own vapor in the gas bubble showed that the driving pressure ratio for 50% positive results was 4.3. High-speed photographic coverage of Compound R, ethyl nitrate, and *n*-propyl nitrate in which glass U-tubes instead of metal tubes were used showed both the liquid and vapor phase of Compound R participating in the explosion. This contrasted with the ethyl nitrate and *n*-propyl nitrate photographs where it could be seen that the explosion occurred only in the vapor phase. These observations were supported by the damage sustained by the stainless-steel U-tubes during the standard tests. During tests with Compounds R and T and mixtures containing these materials, 5 to 8 cm (2 to 3 in.) of tubing were completely fragmented in positive tests. During positive tests with ethyl nitrate, only a small portion of the tubing next to the crimp was ruptured. Additional tests were conducted where the Compound R in the gas/vapor bubble prior to the test was diluted with dry air, and the boundary in a graph of dilution vs. pressure ratio could be drawn on a graph.

Six tests were conducted on Compound T under its own vapor in the gas bubble and the driving pressure ratio to cause 50% positive results was 4.4. These results contradicted earlier reports that Compound T was more sensitive than Compound R. Both Compounds R and T are very sensitive materials. The Wenograd test indicated that Compound T was significantly more sensitive than Compound R. However, the U-tube test did not show this difference. Additional tests were conducted for mixtures of Compound R or T with TNM, N_2O_4 , or N_2F_4 . Mixtures containing up to 23 to 30% Compound R or T in N_2O_4 appeared to be safe to handle on the basis of U-tube tests.

3.5.6 Electrostatic Discharge Sensitivity of Difluoroamino Compounds

In the electrostatic discharge (ESD) test, TVOPA was negative at 1 J, but positive at 2 J.

3.6 Explosive Performance of Difluoroamino Compounds

3.6.1 Detonation Velocity of Difluoroamino Compounds

LVDs propagate at velocities only slightly supersonic with respect to the unreacted liquid and may be very easily initiated in some liquids. A hypothesis based on shock wave interactions and Mach reflections was proposed to explain the initiation and propagation of LVD in the card gap test, but certain anomalous effects were noted with difluoroamino compounds [158]. Theories proposed for LVD require that the container wall sound speed be greater than that of the liquid explosive. This prediction was tested using lead tubes with 1,2-difluoroaminopropane, a liquid known to sustain normal- and low-velocity detonations. Because of the low sound velocity, it was expected that weak initiating shocks would not yield LVD in lead, though identical shocks would in steel. Unexpectedly, there was definite evidence of LVD propagation even in lead pipes [159].

Detonation shock temperatures for liquid TNT, NM, $F_2NCH_2CH(NF_2)CH_3$ (= 1,2-DP), $H_3CC(NF_2)_2CH_3$ (= 2,2-DP), $F_2NCH_2CH(NF_2)CH_2CH_3$, and $F_2NCH_2C(CH_3)_2NF_2$ were calculated as functions of pre-shock temperature ($278 < T < 313$ K) and shock pressure (0–200 kbar) using a constant heat capacity (C_v) model and a $C_v = f(T)$ model [160]. For NM and the alkyl difluoroamino liquids, there was very little diversion for various pre-shock temperatures. For the alkyl difluoroamino liquids, there was little difference between isomers and homologs. The higher C_v of the bis(difluoroamino)butanes was almost exactly offset by their lower initial density.

The detonation velocities of 1,4-bis(difluoroamino)butane, CAS RN [16096-78-9], 1,3-bis(difluoroamino)butene-2,3, $F_2NCH_2CH=C(CH_3)NF_2$, CAS RN [29369-65-1], 1,2,3,4-tetrakis(difluoroamino)pentane, $F_2NCH_2CH(NF_2)CH(NF_2)CH(NF_2)CH_3$, CAS RN [15270-10-7], and their mixtures with TNT were measured and compared to their analogs with nitro groups instead of difluoroamino groups [161, 162]. The relative ranking of the three compounds within each group was the same.

3.6.2 Critical Diameter of Difluoroamino Compound Detonations

Detonation studies on the isomers 1,2-DP and 2,2-DP including shock sensitivity of the liquid phase, adiabatic self-heating of the liquid phase, and the mechanism and kinetics of thermal decomposition of the liquid phase established that both 1,2- and 2,2-DP detonate at velocities of 5–7 mm/ms and have failure diameters of less than 10 mm [163]. The thermal decomposition of 1,2-DP/nitrobenzene solution over the range 449–460 K (176–187°C) was found to be autocatalytic.

During one period of the SRI Sensitivity Fundamentals program, the critical diameter for propagation of detonation in 1,2-DP and 2,2-DP was measured in a wedge test [154]. The failure diameter of 2,2-DP was 4 mm, whereas the failure diameter of 1,2-DP was 1.6 mm. This is an unusually small critical diameter.

Failure diameters and shock reaction times were determined for all four DP isomers and some of the bis(difluoroamino)butanes, including two homologs. The failure diameter during a detonation is indicated by a drop from the Chapman-Jouguet (C-J) velocity (6 mm/ μ s) to about one-third this value. The difference between the failure diameters of the vicinal (for 1,2-DP: 1.6 mm) and geminal (for 2,2-DP: 4.0 mm) difluoroamino compounds presented a striking example of the dependence of a transient detonation characteristic on isomeric structure [164]. The reaction times for the difluoroaminobutanes were indistinguishable from those of the homologous propanes, but the failure diameters were several times larger (IBA and 2,3-DB; 9.5 mm).

Compounds R and T were capable of propagating an explosion in very-small-diameter charges [126]. The velocity of the propagation was unexpected, being considerably lower than the sonic velocity, but much higher than traditional deflagration propagation rates. These “explosions” did have sufficient energy, however, to fragment very strong tubing, the wall thickness of the capillary tubing being one-half of the ID. A 3-foot length of stainless-steel hypodermic tubing (0.007-in. ID and 0.014-in. OD) was loaded with liquid Compound T and the ends were sealed with clamps made from a 1/4-in. bolt and two tubing sleeves. The length of tubing was placed inside a polyethylene bag and then struck lightly near one end with a small hammer. The entire length of tubing was fragmented. The average explosion propagation velocity was 187 m/s. This value indicated that propagation by means of a CJ shock wave was not involved in these explosions. A much higher velocity would be expected for a CJ detonation and self-supporting shock wave. A possible explanation is a chain reaction of initiations at local “hot spots” caused by adiabatic compression of small gas bubbles in the liquid, causing LVDs.

3.6.3 Initiation of Difluoroamino Compound Detonations

Reaction times for shock initiation were measured for liquid explosives using a high-speed smear camera and a modified gap test. In all cases the reaction times decreased as the initiating shock pressure increased in the range 70 to 130 kbar and as the pre-shock temperature was raised in the range 278–313 K (5–40 °C). For constant shock pressure, the reaction time of 1,2-DP was significantly less than that of 2,2-DP [165]. Similarly, the reaction time of 1,2-bis(difluoroamino)butane was significantly less than that of 2,2-bis(difluoroamino)butane. It was proposed that vicinal compounds decompose faster than geminal compounds because vicinal compounds can undergo a low-activation-energy, exothermic elimination of HF.

3.7 Toxicity of Difluoroamino Compounds

Organic NF_2 compounds were tested for acute oral and/or inhalation toxicity in rats [166]. As a class the difluoroamines were toxic enough to warrant special handling, especially with respect to vapor inhalation. No meaningful pathological data could be collected. The acute oral toxicities of the difluoroamine compounds correlated roughly with that of fluoride ion. There was no systematic difference in toxicity between the vicinal and geminal bis(difluoroamino) compounds. See also [167].

The acute toxic properties of 2,3-bis(difluoroamino)propyl acrylate (NFPA), 1,2,3-tris[1,2-bis(difluoroamino)]ethoxy propane (TVOPA), tris(difluoroamino)fluoromethane (Compound R), and pentafluoroguanidine (PFG) were evaluated in rats and mice by the inhalation, i.p., and intragastric routes of administration [168–170]. The i.p. LD50s in rats were 25, 215, 140, and 155 mg/kg for NFPA, TVOPA, Compound R, and PFG, respectively. There was little interspecies difference in toxicity.

Further studies of TVOPA toxicity in rats, dogs, and monkeys emphasized *in vivo* and *in vitro* degradation of the compound and its action at the cellular level [171, 172]. A very low rate of TVOPA hydrolysis in aqueous solutions was determined in earlier experiments. The assumption that degradation in biological media would not differ significantly from *in vitro* buffered media was incorrect. TVOPA or early organic degradation products have direct toxic action. Inorganic degradation products influence the delayed effects of TVOPA, but are not responsible for death at high doses.

One of the penalties for developing more energetic propellants and explosives using fluoro- and difluoroamino-group-containing binders and plasticizers is the toxicity not only of the propellant itself, but also the toxicity of HF in the exhaust. An attempt was made to reduce the amount of HF in exhaust by adding calcium disilicide (CaSi_2) to the propellant formulation [173].

3.8 Applications of Difluoroamino Compounds

Difluoroamino compounds were considered mostly for energetic binders and energetic plasticizers in solid propellants. Attempts to use them as liquid monopropellants were less successful. Many patent applications have been filed in connection with the use of liquid alkyl difluoroamino compounds as rocket propellants. However, the only practical use found for them was as plasticizers for solid propellants, as described in the chapters on TVOPA and SYEP. Listed here are only a few examples for the use of alkyl difluoroamino compounds in monopropellants. Additional proposed applications as monopropellants are described in *Encyclopedia of Monopropellants*, but none of them has ever flown.

Alkyl difluoroamino compounds are soluble in White Fuming Nitric Acid (WFNA) or Red Fuming Nitric Acid (RFNA). These mixtures are safer to handle than the undiluted difluoroamino compounds and have higher specific impulses as monopropel-

lants than underoxidized alkyl difluoroamino compounds. High-energy, stable, insensitive liquid monopropellants can be formulated that are composed of alkyl difluoroamino compounds and fuming nitric acid. These propellants provide specific impulses $>280 \text{ lb}_f \text{ s/lb}_m$ at $P_c = 6.8 \text{ MPa} = 1000 \text{ psia}$, low sensitivity to impact and adiabatic compression, and good thermal stability [174]. For example, a sample of DP was added to 100% HNO_3 (WFNA). Immediate solution occurred with no chemical reaction indicated by heat release or gas evolution. Examination of the IR spectrum of this solution showed that DP was present substantially unchanged. Upon standing for many days at room temperature, no change in the composition could be detected. The drop weight sensitivity (Olin Mathieson Drop Weight Tester) of this composition was 30–40 kg-cm. This indicates a remarkably low sensitivity for a monopropellant of this energy content. A compression sensitivity value of 21 kg-cm/mL was obtained for this mixture (JANAF Test Method No. 5). This value is compared with values of 6.7 for PrNO_3 and 10.4 for MeNO_2 , both low-energy monopropellants considered to be insensitive. The thermal stability or “self-heat” temperature of this mixture, determined per JANAF Test Method No. 6, with a heating rate of $2.8^\circ\text{C}/\text{min} = 5^\circ\text{F}/\text{min}$, was $411 \text{ K} = 130^\circ\text{C} = 280^\circ\text{F}$.

Dinitramide Oxidizers

1 Ammonium Dinitramide (= Dinitramide) and Ammonium Nitroformate

1.1 Introduction

This chapter deals mostly with ammonium dinitramide (ADN) and other dinitramide salts, but a smaller section on ammonium nitroformate has been added at the end. If this section on ammonium nitroformate had not been included here, it would have been placed in the chapter “Hydrazinium Salts.”

Replacing hydrogen in ammonia with electron-absorbing groups ($-\text{NO}_2$, $-\text{NO}$, $-\text{C}\equiv\text{N}$) draws electrons away from the remaining $\text{N}-\text{H}$ bonds and makes them easier to split, making the molecule more acidic. This progression can be seen when comparing the pK values of nitramine and dinitramine. Of the two, dinitramide – $\text{HN}(\text{NO}_2)_2$, dinitramidic acid, dinitraminic acid, nitronitramide, CAS RN [114045-20-4] – is the more acidic and forms salts with a wide range of metals and bases. A similar progression of increasing acidity has been observed when replacing one, two, or three hydrogen atoms in methane with a nitro group (see *Encyclopedia of Oxidizers*, chapter “Nitromethanes”).

Dinitramidic acid is a very strong mineral acid, having a pK_a value of -5.6 and being thermally labile. It forms stable salts with almost all bases, ammonia, metals, tertiary amines, melamine, cubane tetraamine, dinitro azetidine, and more. The dinitramide salts are more stable than the parent acid and the related covalently bound N,N -dinitro derivatives such as alkyl dinitramines. The higher stability of ionic dinitramide salts is due to the fact that the overall negative charge is distributed by resonance over the entire molecule, thereby imparting a higher $\text{N}-\text{N}$ bond order (Section 3.10.1).

Figure 1 shows the structural formula of ADN.

Figure 1: Structural formula of ammonium dinitramide.

1.2 Nomenclature

The parent acid of ADN, $\text{HN}(\text{NO}_2)_2$, CAS RN [114045-20-4], is variably called dinitramine, dinitramide, dinitramidic acid, dinitraminic acid, *N*-nitronitramide, or dinitroamide, but the correct name, a good tongue twister (used by *Chemical Abstracts* and the International Union of Pure and Applied Chemistry [IUPAC]), is 1,1,3,3-tetraoxo-1,2,3-triazapropene.

Because many salt names of oxyacids end with “-ate,” salts formed from dinitramide should be called dinitramidates, but this nomenclature is not widely accepted. Most researchers prefer to call the salts dinitramides. In French, ADN is called *dinitroamidure d’ammonium*.

It has been argued [1] that the name “amide” should be reserved for $-\text{NH}_2$ derivatives in which only one hydrogen atom on the NH_3 is substituted by a functional group, e.g., acetamide H_3CCONH_2 . The compounds with two hydrogen atoms substituted by functional groups are called imides, e.g., $(\text{H}_3\text{CCO})_2\text{NH}$, acetimide. Hence, a more appropriate name for salts with the $(\text{O}_2\text{N})_2\text{N}^-$ anion would be dinitrimide salts.

1.3 Summary Publications on Ammonium Dinitramide

Many publications on ADN as a rocket propellant emphasize the environmentally friendly composition of the exhaust products, which are less toxic, less corrosive, and less damaging to the ozone layer than the exhaust from propellants based on ammonium perchlorate (AP) [2].

The very best summary on the production, physical properties, chemistry, and applications of energetic dinitramides published to date is a book written by Ang and Santhosh [3]. This book is a very thorough summary of all information published up to that time and contains a detailed list of references (including complete titles of the publications referenced, which makes the list of references more useful, similar to the format used in our book).

There are several good survey and summary publications on the application of ADN as a rocket propellant, including [4]. Propellants based on ADN are more environmentally friendly compared to solid propellants based on AP. There are, however, some drawbacks: ADN is relatively shock sensitive, and it is also sensitive to light and moisture. The Langlet, Wingborg, and Oestmark 1997 paper [4] also presents a comparison of the specific impulse of composite propellants based on ADN and other oxidizers such as ammonium nitrate (AN), AP, hexanitrohexaazaisowurtzitane (CL-20), and hydrazinium nitroformate (HNF), with hydroxyl terminated polybutadiene (HTPB) as a binder. The friction sensitivity of ADN is much lower than that of 1,3,5-trinitrotriazine (RDX). The impact sensitivity of ADN is of the same magnitude as that of RDX but varies a great deal with the shape of the particles, e.g., prilled ADN is nearly twice as insensitive as RDX.

ADN and HNF are two new oxidizers that compete for applications both in solid propellants and in monopropellants. It depends on the application one has in mind before one can decide which of the two would make a better rocket propellant. For solid propellants, ADN has the advantage of higher oxygen content, but it has the disadvantages of hygroscopicity and worse sensitivity [5]. In this study, the sensitivity, density, and thermal stability of ADN and HNF were measured and compared. The results showed that the thermal stability is of major concern for both ADN and HNF. ADN has very unusual thermal stability behavior, being less stable at 333 K (60 °C) than at 343 or 353 K (70 or 80 °C). This paradox is very difficult to explain. To increase the thermal stability, a stabilizer will probably be needed for both ADN and HNF. From the impact sensitivity testing, it was found that both ADN and HNF should be considered to be sensitive materials. HNF does not meet the United Nations criteria with respect to friction sensitivity, and thus it cannot be transported without making special arrangements, such as shipping it covered with excess water.

See also [6–8]. Some survey papers are quite general and do not provide many hard facts, but others are a good introduction to the topic of ADN and related dinitramide salts as oxidizers for rocket propellants and explosives.

An excellent overview of the synthetic routes and properties of ADN and other dinitramide salts, with 56 references, is the summary by Venkatachalam, Santhosh, and Ninan [9].

Another excellent summary of applications of ADN is the publication by Vandel, Lobanova, and Loginova, [10] with 79 valuable literature references. Several sections in this chapter of the book at hand draw on information taken from that publication. Originally suggested as oxidants for rocket propellants and explosives, dinitramide compounds have significantly expanded their application areas, and this occurred not only in military but also in non-military applications.

The researchers at the Swedish organizations who have been leading the commercial ADN development continue to publish very good summaries on applications of ADN in monopropellants and in solid propellants [11–15].

1.4 History of the Discovery of Ammonium Dinitramide

The precursor to dinitramine (dinitramide, dinitramidic acid), nitramine (nitramide, nitroamide) H_2NNO_2 is very unstable and is not suitable as a rocket propellant. Its salts are more stable, depending on the stability of the cation.

There are many descriptions in the literature for preparation of nitramine under conditions very similar to those leading to dinitramides. It seems that if the former chemists had only varied their operating conditions and had had better methods for molecular structure analysis, ADN and its parent acid might have been discovered decades earlier.

ADN was first discovered on 18 May 1971 at the N. D. Zelinsky Institute of Organic Chemistry in Russia [1, 16, 17], but it was kept a closely guarded secret until its independent rediscovery in the United States by Bottaro and coworkers in 1989 [18]. Part of the earlier Russian work on dinitramide was not published until the early 1990s. During the period 1971–1975, more than one hundred different dinitramidic acid salts were prepared and characterized in Russia in secret.

In the early 1980s, the U.S. Office of Naval Research began a search for improved energetic materials. This program led to studies on the development of cubane-based explosives, fuels, and oxidizers. In 1988, while developing an improved route to dinitramines for application on cubanes, SRI International synthesized the dinitramide molecule, the parent of ADN, and prepared cesium dinitramide by a β -elimination reaction starting with 1-(*N,N*-dinitramino)-2-trimethylsilane and catalyzed by cesium fluoride [19]. In true line with instructions from IUPAC, dinitraminic acid was called 1,1,3,3-tetraoxo-1,2,3-triazapropene [20], or dinitramide for short. Several methods for making dinitramide salts were later patented, and these were the first patents for ADN production filed in the United States [21, 22]. In the United States, at one time SRI owned the composition-of-matter patent for all dinitramide salts. SRI granted licenses to the right to synthesize ADN to other entities and was seeking a commercial partner for further development.

Following publication of the patents in 1991, rumors began circulating that the USSR had already used ADN in some of their missile systems. These rumors were confirmed in 1993 when Z. Pak of the Lyubertsy Soyuz Science and Production Association presented a paper at an American Institute of Aeronautics and Astronautics (AIAA) meeting describing some of their work [2]. The development work in the former Soviet Union was later described in a 1995 newspaper article [23]. ADN is recognized as a potential revolutionary replacement for AP in missile systems [24]. The use of ADN can give propellants with high specific impulse, and ADN is environmentally benign and degradable. Once spilled, the dinitramide anion is not as persistent as the perchlorate anion.

All developments in the Soviet Union were of a secretive nature, and, presumably, only a small part of the work on ADN was declassified after dinitramide salts were synthesized by U.S. researchers in 1990. The indubitable attractiveness of the ammonium (ADN), potassium (KDN), and other dinitramide salts as components in various defense applications gives reason to believe that, even as of 2009, the available information (both domestic and foreign) was only the “visible part of an iceberg” [10].

As far as availability of ADN is concerned, the lead in ADN production and application development in Sweden has continued for many years and resulted in some spectacular successes, such as the first firing of a non-hydrazine/non-hydrogen peroxide monopropellant thruster in a satellite in Earth orbit. Several U.S. government agencies, including the Energetics Manufacturing Technology Center at Indian Head, Maryland, have taken steps to achieve a broader ADN manufacturing base

in the United States by sponsoring government contracts and procuring sample quantities, but the U.S. market for ADN is very limited, and profit-motivated industry was slow to respond. The goal was to develop the technology to eventually reduce the manufacturing cost of ADN from between \$3000/lb and \$5000/lb for laboratory scale quantities to less than \$100/lb for pilot scale production quantities [25]. When the National Aeronautics and Space Administration's Glenn Research Center announced in 2008 that they would start procuring ADN from Sweden, a critical discussion erupted on the internet about the lagging U.S. industry being unable to supply this important chemical from domestic sources.

ADN is available in commercial quantities from Eurenco Bofors in Sweden. Many foreign countries have started their own ADN production efforts and are competing with Sweden and the United States [26]; that includes prilling and after-treatment processes to reduce hygroscopicity.

2 Production of Ammonium Dinitramide

There are many different methods for preparation of dinitramide salts, starting with either inorganic or organic chemical ingredients as feedstock. Most of the methods described here end up with ADN, but some create the free dinitramidic acid as an unstable intermediate in a nitration reaction, from where it is easy to prepare any salt desired by neutralizing it with the appropriate base in a subsequent neutralization reaction.

Several very good summaries of the various methods (starting with either inorganic or organic reactants) for production of ADN and similar dinitramides have been published. The most authentic is the one by Lukyanov and Tartakovsky, two of the original discoverers of dinitramidic acid [1]. This publication includes a firsthand account of the work that led to the discovery of dinitramidic acid and efforts to synthesize and characterize a host of dinitramidic acid salts with a variety of bases. It also includes a very detailed summary of the more than twenty synthesis routes leading to dinitramidic acid, including some of the more circuitous routes that are no longer used. Many of the earlier synthesis routes used organic dinitramide intermediates that were then split under alkaline conditions. Now that they are readily available in industrial quantities, ammonium, potassium, or cesium dinitramides can be used in the synthesis of many organic dinitramide compounds.

The methods of preparation of dinitramides can be classified into four groups:

1. The first group is the formation of alkyl *N,N*-dinitro derivatives $R-N(NO_2)_2$ and subsequently the cleavage of the $R-N$ bond, leading to the dinitramide anion:

2. The second method of synthesis is based on inorganic synthetic routes involving direct nitration of NH_3 or NH_2NO_2 using either NO_2BF_4 or N_2O_5 , followed by reaction with a base:

3. The third method involves nitration of deactivated amines such as $\text{NH}_2\text{SO}_3\text{H}$, NH_2NO_2 , NH_2CONH_2 , or $\text{NH}_2\text{COOCH}_3$ using strong nitrating agents such as NO_2BF_4 or N_2O_5 to give dinitramidic acid:

where X can be $-\text{SO}_3\text{H}$, $-\text{NO}_2$, $-\text{CONH}_2$, or $-\text{COOR}$. The most commonly used method is the nitration of sulfamic acid.

4. The fourth method consists of metathetical reactions of the already synthesized dinitramide salts with respective metal salts:

where X can be $-\text{OH}$, Cl , or $-\text{HSO}_4$, and M and M' are metal or amine base cations.

An excellent overview of the synthetic routes leading to ADN published by Venkatachalam, Santhosh, and Ninan in 2004 [9] gives an overview of the yields one can expect from the various methods for preparation of ADN, depending on which reactants one starts (Table 1):

Table 1: Yield of ADN preparation depending on type of starting reactants.

Rxn. No.	Starting material	Nitrating agent	Reaction temperature		Yield %	References
			K	°C		
1	$\text{Me}_3\text{Si}(\text{CH}_2)_2\text{NCO}$	$\text{NO}_2\text{BF}_4/\text{HNO}_3$	<273	<0	25	[20]
2a	NH_2NO_2	NO_2BF_4	253	-20	60	[27]
2b	NH_2NO_2	N_2O_5	253	-20	<1	[27]
2c	NH_2NO_2	$\text{NO}_2\text{HS}_2\text{O}_7$	233	-40	53	[28]
3	$\text{NH}_2\text{COONH}_2$	NO_2BF_4	273	0	15	[21]
4a	NH_3	NO_2BF_4	195	-78	25	[29]
4b	NH_3	N_2O_5	195	-78	15	[29]
4c	NH_3	$\text{NO}_2\text{HS}_2\text{O}_7$	195	-78	15	[29]
5	$\text{NH}_2\text{CONHNO}_2$	NO_2BF_4	233	-40	20	[30, 31]
6a	$\text{NH}_2\text{COOC}_2\text{H}_5$	N_2O_5	225	-48	70	[32]
6b	$\text{NH}_2\text{COOC}_2\text{H}_5$	NO_2BF_4	213	-60	60	[33]
7	$\text{HN}(\text{CH}_2\text{CH}_2\text{COOEt})_2$	NO_2BF_4	<273	<0	31	[34]
8	$\text{HN}(\text{CH}_2\text{CH}_2\text{CN})_2$	NO_2BF_4	263	-10	60	[35]
9	$\text{NH}_2\text{SO}_3\text{NH}_4$	$\text{HNO}_3/\text{H}_2\text{SO}_4$	228	-45	60	[36]

A summary published by Wang et al. [37] lists ten different methods for preparation of dinitraminic acid and its salts, including the following:

1. reaction of β -substituted *N*-alkyl-*N,N*-dinitroamide salts;
2. cation exchange of dinitramide salts;
3. reaction of ADN with a strong base (eliminating ammonia by sparging);
4. reaction of $\text{XN}(\text{NO}_2)_2$ with ammonia;
5. reaction of urethanes with carbonic acid anhydrides and anhydrous HNO_3 , then a base to yield *N*-(alkoxycarbonyl)-*N*-nitroamide salts, followed by reaction with a nitronium compound;
6. reaction of nitramides with a nitrating agent to form dinitramides;
7. reaction of an aliphatic isocyanate with NO_2BF_4 and HNO_3 to form *N,N*-dinitramines, which can be further reacted with a base to form dinitramides;
8. reaction of ammonium carbamate with a nitrating agent;
9. reaction of ammonia with nitronium compounds;
10. reaction of 2-(trimethylsilylethyl)-*N,N*-dinitramines with CsF to form cesium dinitramide [20].

Among the ten methods listed above, only methods 5, 6, and 10 have high yields. The yields of the other methods are less than 30%.

ADN is still difficult to make in large quantities, and scaling up the operation to a kilogram output level is already a substantial achievement and requires operating at low temperatures [38]. Regardless of which production process is used, one must have effective methods for isolation and removal of by-products to obtain a good yield of a pure main product [39].

2.1 Production of Ammonium Dinitramide from Inorganic Starting Materials

2.1.1 Different Types of Nitrating Agents

Different types of nitrating agents can be used for the preparation of ADN [40]. Instead of trying to isolate the product as the very soluble ADN, it is easier to isolate the dinitramide salt in the form of the poorly soluble guanidinium dinitramide, which precipitates, is filtered, and can later be converted to ADN [41].

2.1.2 Starting with Ammonia

There are many different methods to synthesize ammonium dinitramide $\text{NH}_4\text{N}(\text{NO}_2)_2$, ADN. Most syntheses proceed over several intermediate steps, but only the reactions of ammonia with dinitrogen pentoxide or with nitronium tetrafluoroborate lead to ADN directly in one step. The most direct method of synthesis is based on an inorganic synthetic route involving the direct nitration of NH_3 or NH_2NO_2 at 253 K (-20°C) using

either NO_2BF_4 or N_2O_5 , followed by reaction with ammonia as shown below [21]. This patent describes two different methods, one starting with ammonia:

The other method described in [21] is a β elimination reaction of 2-trimethylsilylethyl-N,N-dinitramine $(\text{CH}_3)_3\text{Si}(\text{CH}_2)_2\text{N}(\text{NO}_2)_2$ with an ammonium salt catalyzed by cesium fluoride. Other nitrating agents instead of NO_2BF_4 that may be reacted with nitramine include $(\text{NO}_2^+)_2$ ($\text{S}_2\text{O}_7^{2-}$), NO_2AlCl_4 , N_2O_5 , $\text{N}_2\text{O}_2\text{F}$, NO_2PF_6 , NO_2AsF_6 , NO_2SbF_6 , acetyl nitrate, trifluoroacetyl-nitrate, trifluoroacetyl nitrate in combination with catalytic BF_3 , acetone cyanohydrin nitrate in combination with catalytic BF_3 , and any one of these in combination with white fuming nitric acid.

Another direct nitration of ammonia operates at lower temperatures, 253 to 153 K (-20 to -120°C) [29]. The preferable temperature range is from 233 K (-40°C) to about 193 K (-80°C). The nitrating agents are nitronium salts or covalently bound compounds containing the $-\text{NO}_2$ group. Suitable nitronium compounds are those with BF_4^- , NO_3^- , HS_2O_7^- , AlCl_4^- , F^- , PF_6^- , ClS_2O_6^- , F_2PO_2^- , AsF_6^- , SbF_6^- , FS_2O_6^- , ClO_4^- , $\text{S}_2\text{O}_7^{2-}$, SiF_6^{2-} , or SO_3F^- as the anions. For this procedure, the nitronium-containing compound is first dissolved in an aprotic liquid such as diethyl ether, methylene chloride, chloroform, carbon tetrachloride, methyl ether, a halocarbon, acetonitrile, ethyl acetate, or sulfolane. The process can be conducted as a batch process, and at the end of the reaction period, the reaction mass is allowed to warm up to room temperature while a basic condition is maintained by keeping it under an ammonia atmosphere. The nitronium compound should be free of nitrosonium compounds, NO or NO_2 , which interfere with the formation of dinitramide. The reaction must be carried out under anhydrous conditions.

The ammonia can be dissolved up front in an aprotic liquid to form a solution that is then mixed with a nitronium-containing compound solution to form ADN, or it can be bubbled through the solution of the nitronium compound. It is important that the reaction temperature not be lower than 153 K (-120°C) because the formation of the covalently bonded and less stable nitramide may be more favored at a temperature lower than about 153 K (-120°C). In one variation of the process, the gaseous ammonia reactant is fed into the reactor at a rate sufficient to maintain the desired low temperature of the reaction mixture. The ammonia feed rate may vary from about 0.1 L/min to about 3 L/min per liter of the aprotic liquid/nitronium-containing compound solution. The total amount of ammonia used in the reaction must be sufficient to provide an excess of ammonia above the stoichiometric requirements at the end of the reaction (at least 4 mol ammonia for 2 nitronium ions).

Preferably, the gaseous ammonia reactant is introduced into the reactor below the surface of the liquid and allowed to bubble through the liquid, or it is added above the liquid and allowed to condense or be absorbed into the reaction mixture. The liquid is stirred during the ammonia addition to further facilitate dissolving of the ammonia and achieve intimate contact between the reactants. The ammonia may also be added

from above as liquid ammonia. When the ammonia is added to the reaction mixture as a gas, it must be precooled to just above 240 K (-33°C), its condensation point. The reaction may be carried out as a batch process or on a continuous basis with batch or continuous extraction of portions of the reaction mass. After 1–8 h, the reaction mixture is maintained under basic conditions by adjusting the total quantity of ammonia; the stirring is continued, and the temperature of the reaction mass is allowed to rise slowly up to room temperature. The flow of ammonia into the reactor during this heating period may be adjusted to keep the overall reaction mixture basic, as well as to maintain a blanket of ammonia gas over the reaction mixture.

The disadvantage of the above ADN production methods is that they require nitronium tetrafluoroborate (CAS RN 13826-86-3) as the nitrating agent, which is available commercially but can be quite expensive. Commercial $\text{NO}_2^+\text{BF}_4^-$ often contains varying amounts of NO^+BF_4^- . Removal of the nitronium ion NO^+ from $\text{NO}_2^+\text{BF}_4^-$ is difficult. Therefore, pure nitronium tetrafluoroborate should be prepared directly from urea-treated purified HNO_3 . There are several examples of how to prepare NO_2BF_4 immediately prior to ADN synthesis. Nitronium tetrafluoroborate may be formed by the slow addition of BF_3 to a solution of HF and ethyl nitrate in methylene chloride or nitromethane. In one example, nitronium tetrafluoroborate (free of nitronium ion), was prepared by the slow addition of 100 g (1.5 mol, excess) of BF_3 to a solution of 8.8 g (0.44 mol) of HF and 40 g (0.44 mol) of ethyl nitrate in 300 mL of dry nitromethane kept at 263–268 K (10 – 15°C) by adjusting the rate of BF_3 addition. After formation of the nitronium salt was complete, it was allowed to settle, and the nitromethane was decanted. The salt was washed twice with 400 mL of a 1 : 1 mixture of CH_2Cl_2 and CH_3NO_2 , and then once with 400 mL of CH_2Cl_2 , and was finally suspended in 400 mL of CH_2Cl_2 .

For making ADN, the CH_2Cl_2 liquid containing NO_2BF_4 salt was stirred and cooled to 195 K (-78°C), and 35 g (2.059 mol, excess) of anhydrous NH_3 was bubbled into the slurry over a 2-h period. The reaction mass was stirred for 12 h, during which time it was allowed to warm to room temperature. The product solids were allowed to settle, and the CH_2Cl_2 was decanted. The remaining solids were then washed with 400 mL of CH_2Cl_2 , and the mixture was then evaporated under vacuum to dryness. Next, 150 mL of acetone was added, the solids digested for 1 h, and then 150 mL of ethyl acetate was added to decrease the solubility of NH_4BF_4 and NH_4NO_3 , which were separated from the solution. The filtrate was concentrated to dryness to give 9 g of a pale brown solid that, when recrystallized from 70 g of *n*-butanol, gave 5.5 g of ADN, with a yield of 21 % of theory.

A more economical nitrating agent is “nitronium nitrate” (= dinitrogen pentoxide, N_2O_5). It can be formed by passing ozone through a stirred solution of N_2O_4 in CH_2Cl_2 , for instance by dissolving 12.3 g of N_2O_4 (0.13 mol) in 300 mL of dry CH_2Cl_2 and cooling the solution to 195 K (-78°C). In this example, an ozone stream was passed through the solution, while stirring, until the solution was dark blue, resulting in the formation of a solid precipitate of nitronium nitrate. Oxygen was then bubbled through the solution to remove excess O_3 . To the nitronium nitrate-containing liquid was added 6 g

(0.35 mol) of anhydrous NH_3 over a 30-min period, while the mixture was maintained at 195 K (-78°C) with stirring. Stirring was continued for 2 h at 195 K (-78°C), and then the reaction was allowed to warm to room temperature. The CH_2Cl_2 was evaporated, and the remaining solids were washed with 100 mL of CH_2Cl_2 . The ADN salt product was extracted twice with 50 mL of acetone. The acetone extracts were concentrated to dryness to yield 1.77 g of a light yellow solid, which was recrystallized from *n*-butanol to give 1.16 g of ADN with a 15% yield. Changing the operating temperature to 243 or 233 K (-30 or -40°C) gave ADN yields of only 5%.

Another nitrating agent is nitronium hydrogen pyrosulfate, which can be made by mixing SO_3 and anhydrous HNO_3 in dry CH_2Cl_2 at room temperature. In one example, 40 g (0.5 mol) of SO_3 was slowly added to 15.5 g (0.25 mol) HNO_3 in 400 mL of dry CH_2Cl_2 while stirring, and the mixture was allowed to reflux to conduct away the heat of reaction. After the exotherm, the resulting nitronium salt was stirred for 2 h at room temperature, during which time it changed from a gelatinous state to a crystalline material. The slurry was cooled to 195 K (-78°C), and 30 g of anhydrous ammonia was introduced over 2 h. The mixture was stirred for 12 h while it was allowed to warm to room temperature. Excess NH_3 was blown out with argon; 100 mL of isopropanol was added, in which the ADN is soluble; and this mixture was stirred for 1 h and then was allowed to settle and was decanted. The extraction solvent was stripped off and concentrated to yield about 5 g of solids, which, when recrystallized from *n*-butanol, gave 2.8 g of ADN, with a 20% yield.

Reactions of ammonia with the lower nitrogen oxides (state of oxidation of nitrogen lower than +5, as in N_2O_5) have been investigated extensively for over one hundred years, but the aspect of potential formation of nitramine as an intermediate has been considered for only a few years.

2.1.2.1 Mechanism of ADN Formation from Ammonia and Dinitrogen Pentoxide

The reaction of dinitrogen pentoxide with ammonia leads to the formation of AN, nitramide (NH_2NO_2), and ADN. The yields for the latter two are 30 and 13%, respectively. The mechanism of this ADN synthesis was described as a double nitration of NH_3 via the intermediate nitramide and dinitramidic acid [42–44]. Three types of reactions between NH_3 and N_2O_5 seem to be possible to form AN in different molar amounts, whereas the formation of ADN is possible only by one of the three reactions. Due to the catalytic decomposition of the intermediates, H_2O and N_2O are formed as further reaction products and can be identified by infrared (IR) spectroscopy. In addition to the well-known reaction of NH_3 with N_2O_5 , forming ADN, nitramide, and its decomposition products, a third reaction was discovered: the reaction of NH_3 with N_2O_5 , forming AN and N_2O with the same stoichiometry as is observed for ADN synthesis. This reaction was not previously reported in the literature. The operating conditions (sequence of adding the reactants) and temperature were varied systematically, and the ADN yield and the ratio of (unwanted) AN formation to N_2O_5 were measured. The results in Table 2 show that the best ADN yield is obtained by adding N_2O_5 to NH_3 dissolved in chloroform at 261 K (-12°C).

Table 2: Yields of ADN under different reaction conditions and with different molar ratios of AN to N_2O_5 .

No.	Conditions of reaction	Yield of ADN, mol	Mol ratio $n(\text{AN})/n(\text{N}_2\text{O}_5)$
1	NH_3 gas added to N_2O_5	0	1.47
2	Liquid NH_3 added to N_2O_5	0.1	1.34
3	N_2O_5 added to liquid NH_3	0.01	1.00
4	N_2O_5 added to dissolved NH_3 (+7 °C)	0.08	1.32
5	N_2O_5 added to dissolved NH_3 (+20 °C)	0.07	1.18
6	N_2O_5 added to dissolved NH_3 at -22 °C	0.14	1.27
7	N_2O_5 added to dissolved NH_3 (-12 °C)	0.19	1.31

Three types of reactions between NH_3 and N_2O_5 are possible to form AN in different molar amounts, whereas the formation of ADN is possible only by one of the reactions. These results can be explained by the three following chemical equations, R1 to R3:

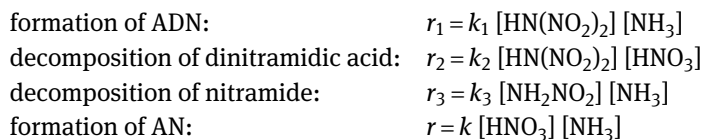

Reaction R2 without any ADN formation is dominant if NH_3 gas is added to the N_2O_5 solution. If NH_3 is added as a liquid, only a small amount of the reactants form ADN due to the reaction R1, but R2 is still the main reaction. In the reverse case, namely the addition of a N_2O_5 solution to liquid NH_3 , R3 is the dominating reaction. By analyzing the gaseous products and the amount of AN formed, the relative contribution of each of these three reactions was identified. The AN and ADN can be separated because AN is not soluble in ethyl acetate. By summarizing the known reactions of NH_3 with N_2O_5 and those of the intermediate products in a reaction scheme, a kinetic model was established for the selectivity of ADN formation and for its dependence on the reaction conditions. Kinetic modeling of the overall reaction scheme led to an equation for the differential selectivity for the formation of ADN. The accuracy of the equation could be confirmed by comparison to experimental measurements. The sequence of events is thus:

First-order reaction rate constants for five partial reactions are expressed and combined to form the model:

first nitration step: $r_0 = k_0 [\text{NH}_3] [\text{N}_2\text{O}_5]$

second nitration step: $r_{0'} = k_{0'} [\text{NH}_2\text{NO}_2] [\text{N}_2\text{O}_5]$

where the species in brackets indicate the molar concentrations of the reactants and products. The decomposition of dinitramidic acid is an autocatalytic reaction accelerated by the presence of nitric acid. Therefore, an excess of ammonia neutralizing the nitric acid is necessary for the formation of ADN.

2.1.3 Formation of Nitramine as an Intermediate and By-Product

There are several publications dating to the 1960s by chemists who came very close to discovering dinitramidic acid and its salts. Although nitramine (nitroamine, nitramide) is not considered a rocket propellant, its formation as an intermediate and unwanted by-product of ADN production deserves some discussion in this book. Nitramine was known long before dinitramidic acid and its salts. It is surprising that chemists working with nitramine in the 1960s did not recognize the potential of forming dinitramidic acid under conditions not much different from those used for making nitramine. They reacted ammonia with nitronium compounds at very low temperatures, but they reported only the formation of nitramide and never recognized the potential formation of dinitramide under very similar conditions. Chemists in the old days lacked the analytical instrumentation to identify dinitramide as a by-product. It has been theorized that by keeping the temperature above 193 K (−80 °C), the unstable nitramide will react with additional nitrating agent to form the desired dinitramide, which is more stable than the mononitramide. The decomposition of nitroamine (nitramine) has been studied in concentrated aqueous perchloric acid, sulfuric acid, and hydrochloric acid over a range of temperatures [45]. In all cases there is a linear correlation between $\log k_1$ and the Hammett acidity function H_0 , with a slope of about 0.35. These results have been interpreted in terms of a rate-determining nucleophilic attack of water upon the protonated nitroamine to give hydroxylamine and nitrous acid, which then react to give dinitrogen oxide. Only after the intermediacy of nitramine in the production of ADN became known did chemists start to take another look at this compound. Nitroamine vapor phase decomposition may also play a role in the decomposition of ADN during its end use in rocket propellants [46].

Nitramide was synthesized for the first time by Thiele and Lachmann in 1894. It is surprising how long it has taken from then until the discovery of dinitramidic acid and its salts. The reaction of ammonia with nitronium salts or N_2O_5 at 77 K (−196 °C) to form nitramide was reported in the early literature [47]. Small (200–300 mg) portions of N_2O_5 cooled to 77 K (−196 °C) were introduced into partially crystallized ammonia under dry nitrogen. The operation lasted 15–30 min. The nitramide was recovered by

extraction of the product with ether and precipitated with petroleum ether or isopentane. Quantities of up to 5 g of nitramide were obtained with yields of 25–30%, based on N_2O_5 . A complete literature review of nitramide chemistry included a few of the reactions (overlooked by early nitramide researchers) leading to dinitraminic acid [48].

The reaction of HNO_3 with $\text{H}_2\text{NSO}_3\text{Na}$ with a contact time of 10–60 min and a temperature of 238 K (-35°C) gave nitramine with a 70% yield [49]. Best results were obtained by neutralization with NaHCO_3 solution.

The reaction between nitryl salts, including NO_2BF_4 , NO_2ClO_4 , NO_2FSO_3 , $\text{NO}_2\text{Cl}_2\text{SO}_3$, or N_2O_5 , and liquid NH_3 at low temperature (77 K; -196°C) gave nitramine [50, 51]. The product was extracted and determined potentiometrically. The ionization of the nitryl salt into an anion and NO_2^+ decreases in the order $\text{NO}_2\text{NO}_3 > \text{NO}_2\text{BF}_4 > \text{NO}_2\text{ClO}_4 > \text{NO}_2\text{FSO}_3 > (\text{NO}_2)_2\text{S}_2\text{O}_7 > \text{NO}_2\text{S}_2\text{O}_6\text{Cl} > \text{NO}_2\text{Cl}$. The decrease is related to the more or less ionic structure of the nitryl salts and has an influence on the nitramine yield and the product mix.

Only after the intermediacy of nitramine in the production and decomposition of ADN became apparent did chemists go back to take another look at this compound, including efforts to interpret its molecular structure, types of bonding, and mechanisms of decomposition [52]. Nitramine decomposes readily in acidic solutions in the presence of catalysts [53].

2.1.4 Starting with Ammonium Carbamate

As an alternative to ammonia, one cheap starting material is ammonium carbamate, which after reaction with NO_2BF_4 forms the dinitramidic acid [27]:

This reaction is best carried out in acetonitrile as the solvent and at moderately low temperature (233–243 K; -40 to -30°C). The theoretical yield is 15%.

The following method does not use special nitrating agents such as NO_2BF_4 or N_2O_5 , but instead uses common nitrating acid, a mixture of anhydrous nitric acid and sulfuric acid, which should make it even more economical than the previously described methods.

In the previously described syntheses of the dinitramidic acid, use was made of very strong oxidizing systems of the type N_2O_5 or NO_2BF_4 . These are relatively expensive and very moisture sensitive and are not suitable for large-scale industrial preparation of ADN. One advantage of the following method is that dinitramidic acid can be prepared by nitration with a common nitrating acid, such as nitric acid/sulfuric acid, or a corresponding inexpensive nitration system [36]. According to this patent, dinitramidic acid can be prepared by nitration of a compound selected from the group consisting of NH_2NO_2 , $\text{NH}_2\text{COONH}_4$, $\text{NH}_2\text{SO}_3\text{H}$, $\text{NH}(\text{SO}_3\text{H})_2$, $\text{N}(\text{SO}_3\text{H})_3$, or reaction products of ammonia and sulfur trioxide with a nitrating acid mixture selected from the group consisting of nitric acid/sulfuric acid ($\text{HNO}_3/\text{H}_2\text{SO}_4$), nitric

acid/oleum ($\text{HNO}_3/\text{H}_2\text{SO}_4/\text{SO}_3$), nitric acid/sulfur trioxide, nitric acid/perchloric acid, nitric acid/phosphoric acid, nitric acid/diphosphorus pentoxide, nitric acid/acetic acid, nitric acid/acetic anhydride, nitric acid/trifluoroacetic acid, or nitric acid/trifluoroacetic anhydride, at a temperature of 248 K (-25°C) or below to form dinitraminic acid. No aprotic solvent for the nitrating agent is required when nitrating with the nitrating acids, which facilitates the subsequent processing.

Dinitramidic acid, once formed, is then neutralized with a base to form the corresponding dinitramide salt. The base can be ammonia, KOH, hydrazine, hydroxylamine, or an alkylamino.

The concentration of dinitramidic acid in the reacting mixture is constantly monitored, and the base is added only when the $\text{HN}(\text{NO}_2)_2$ concentration has reached an optimal level. The continuous analysis of the reacting mixture can be performed by ultraviolet (UV) spectroscopy.

2.1.5 Starting with Sulfamic Acid

Starting with aminosulfonic acid (sulfamic acid) as starting material, ADN was obtained by the process of neutralization, nitration, ammonolysis, and purification [54]. The purity of the product was characterized by IR, UV, and elemental analysis. The effect of nitration reaction temperature and duration on the yield were investigated, and the operating conditions were optimized. ADN was separated and purified by the adsorption on charcoal, and relative conditions were studied, such as the weight of the charcoal, the speed of extraction, the terminal point of washing, and the method of desorption. The purity of ADN was improved to 99.8% ADN without recrystallization and with a yield of 50%.

Dinitramide, the energetic anion in, for instance, guanylurea dinitramide (GuDN), KDN, and ADN, is produced at Eurenco Bofors using the sulfamate method patented by the Swedish Defence Research Agency (FOI). The synthetic route involves fuming nitric and sulfuric acid. In the FOI process, the sulfamate nitration was terminated by water quenching, and then the reaction solution was neutralized with potassium hydroxide. A pure but weak potassium dinitramide solution was produced by adsorption separation on columns. The dilute KDN solution was concentrated prior to ion exchange to produce ADN, which was finally crystallized from ethanol solution. The whole process generated large amounts of waste. Terminating the sulfamate nitration using minute amounts of water and separating the dinitramide from the strong spent acid using guanylurea or its hydrolysis precursor dicyandiamide to obtain relatively insoluble crystalline GuDN made a great improvement in process economics and ecologic impact [55]. This improvement in the sulfamate method also made it possible to recover and possibly reuse the spent acid as high concentration acids, which was not practically possible by the old method. Because of this changeover, waste generation could be reduced by up to 75%.

2.1.6 Starting with Ammonium Sulfamate

For starting products, it is best to use salts that contain a cation of the same type as the cation of the neutralizing agent that is later used for neutralizing the formed dinitramidic acid to dinitramide salt. Particularly preferred are ammonium and potassium salts of the initial substances (e.g., ammonium sulfamate $\text{H}_2\text{NSO}_3\text{NH}_4$ or potassium sulfamate $\text{H}_2\text{NSO}_3\text{K}$), and the neutralization after the nitrating is carried out with NH_3 and KOH , respectively, which provides a direct path to ADN and KDN, respectively.

Dinitramidic acid is not stable in an acidic environment, and the dinitramidic acid content of the reaction mixture rises to a maximum and then decays. The yield deteriorates if the reaction is not interrupted at the correct time. The acid content is checked repeatedly as the reaction proceeds by samples being taken, diluted, and examined by UV spectroscopy. The dinitramidic acid has a maximum UV absorbance at 285 nm. The reaction is interrupted by the reaction mixture being diluted with water during intense cooling, for instance by pouring it into an ice bath. When the neutralization approaches its terminal point, the solution obtains a characteristic green-yellow color.

Another technique of separating KDN from a reaction mixture neutralized with KOH is to vacuum-concentrate the mixture to a dry powder and extract the powder with acetone. Subsequently, 2-propanol is added to the acetone solution, and the extract is evaporated. First, acetone dissipates, and KDN, having low solubility in 2-propanol, precipitates and can be separated from the solution.

For preparing ADN in small quantities, ammonium sulfamate was added in small portions to a mixture containing 98% sulfuric acid and white fuming nitric acid (WFNA) at 238 to 228 K (-35 to -45°C) in a three-necked round-bottom flask with stirring [56]. The mol ratio of sulfuric acid to nitric acid was varied from 0 to 4, and the yield of ADN formation was measured. The initial yield of ADN increased with increase of the sulfuric acid content in the acid mixture and started to decrease again as the reaction time was extended (Figure 2).

The variation of product yield with change in reaction time and total acid concentration was measured to optimize the process. When the ratio $\text{H}_2\text{SO}_4 : \text{HNO}_3$ was 2 : 1, the optimum yield of 45% was obtained in 20 min. If the reaction time was extended to 30 min, the yield dropped to 35%. It is difficult to explain the shape of the curve obtained with a 1 : 1 ratio. With $\text{H}_2\text{SO}_4 : \text{HNO}_3$ ratios of 1 : 1 and 2 : 1, the reaction mixture became very viscous at temperatures below 243 K (-30°C). The Santhosh et al. publication [57] and Santhosh's PhD dissertation [58] also contain clean UV- and IR-spectra and differential scanning calorimetry (DSC) thermograms of ADN produced using this method. The Santhosh PhD dissertation [58] is a genuinely valuable work with discussion of some of the most pertinent aspects related to the synthesis and characterization of several dinitramide salts. The chemistry, mechanism and kinetics of the formation of dinitramide salts by nitration of deactivated amines were investigated in detail. The effects of the sulfuric acid to nitric acid ratio, reaction duration, trace amounts of water, and temperature on the dinitramidic acid yield were measured and

Figure 2: Ammonium dinitramide yield as a function of time for different sulfuric acid to nitric acid ratios. (Reproduced and modified from Santhosh et al. [57]; licensed under Creative Commons License: CC Attribution-Noncommercial-No Derivative Works 2.5.)

optimized. When experiments were carried out using a stoichiometric sulfuric acid to nitric acid mol ratio of 2, a maximum yield of 45% was obtained in 20 min. The acid mixture, however, is very viscous at 233 K (-40°C), hence fast addition of the ammonium sulfamate reactant at a controlled rate becomes very difficult. The evaluation of the thermal and spectral properties along with the adsorption and thermal decomposition characteristics of the dinitramide salts were part of this valuable thesis.

Preparation of dinitraminic acid and its salts by nitration of ammonium sulfamate with fuming nitric acid as a nitrating agent using solid acid catalysts selected from the group consisting of a montmorillonite clay catalyst, metal ion-exchanged K10 montmorillonite clay catalysts, or surface-supported catalysts is supposed to reduce the amount of waste acid generated [59, 60]. The dinitraminic acid is then used for the preparation of ADN by neutralization with ammonia followed by separation of ADN.

Recommended operating conditions for synthesis of ADN from ammonium sulfamate are a nitric acid to ammonium sulfamate molar ratio of 9, a nitric acid to sulfuric acid molar ratio of 6.67, operating temperature of 233 K (-40°C), and reaction time of 45–65 min. [61]. The promised ADN yield is 55% in theory.

The reaction kinetics for the preparation of ADN by the nitration of ammonium sulfamate using mixed acid, followed by hydrolysis, neutralization with ammonia (gas), and extraction using a solvent were studied in order to optimize the yield of ADN [62]. The nitration of ammonium sulfamate was carried out at a temperature of 233 K ($-40 \pm 1^\circ\text{C}$). The yield of ADN is dependent on the formation of dinitramidic acid, an intermediate product formed during the hydrolysis step, and its stability is predom-

inantly dependent on the level of acidity and temperature of the reaction medium. Since the nitration of ammonium sulfamate is sensitive to temperature, the rate of reaction was studied at fixed temperatures with variation of time, keeping all of the other parameters, such as vessel volume, agitator speed, feed rate, etc., constant. In order to find the effect of temperature on the reaction rate and yield, experiments were conducted at other temperatures such as 243 and 223 K (-30 and -50 °C). It was found that the optimum temperature of nitration was 233 K (-40 ± 1 °C) (Figure 3) and that the rate of reaction followed a pseudo second-order process with a rate constant of $0.01113 \text{ min}^{-1}(\text{mol/L})^{-1}$. The reaction time evaluated for 55–60% conversion was about 70–80 min at 233 K (-40 °C).

Figure 3: Effect of temperature on the yield of ADN. (Reproduced and modified from Mandal et al. [62]; Cent. Eur. J. Energ. Mater.; licensed under <https://creativecommons.org/licenses/by-nc-nd/4.0/>.)

During the synthesis of ADN, N-nitration is required to form the $\text{N}(\text{NO}_2)_2$ group, in conjunction with the decomposition of sulfamate. Calorimetric studies to assess thermal variations during the nitration of both K and NH_4 sulfamates, applying a number of different nitration agents ($\text{HNO}_3/\text{H}_2\text{SO}_4$, $\text{HNO}_3/\text{H}_2\text{SO}_4 + \text{H}_2\text{O}$, HNO_3/AcOH , and HNO_3 alone), determined that the heat of decomposition of sulfamates in $\text{HNO}_3/\text{H}_2\text{SO}_4$ at 273 K (0 °C) was greater than at 293 K (20 °C), although a similar trend was not observed in HNO_3/AcOH or HNO_3 by itself [63, 64]. The heats of decomposition in HNO_3/AcOH and in HNO_3 were greater than in $\text{HNO}_3/\text{H}_2\text{SO}_4$ because of how the nitration reagent affects the relative contributions of different pathways to the decomposition process. The heat of decomposition in $\text{HNO}_3/\text{H}_2\text{SO}_4 + \text{H}_2\text{O}$ was less than that in $\text{HNO}_3/\text{H}_2\text{SO}_4$ because the addition of water inhibits both nitration and decomposition by HNO_3 . Under such conditions, however, a second exothermic peak was observed because of the hydrolysis of potassium sulfamate.

2.1.7 Starting with Potassium Sulfamate

The following is an example for nitration of potassium sulfamate [65]: 45 mL of WFNA and 16 mL of sulfuric acid (95%) were mixed and stirred and then cooled to about 243 K (−30 °C) with a mixture of dry ice and dichloroethane. The potassium salt of sulfamic acid was then added in small portions of 0.5–1 g during very powerful agitation. The viscosity increased significantly as the reaction proceeded when KHSO_4 precipitated. The amount of dinitramidic acid formed was checked by taking off 1 mL of the solution, diluting it to 1000 mL, and examining it by means of a UV spectrometer at 285 nm. The reaction was interrupted to obtain an optimum yield of the acid. At this point, an additional 17 g of potassium sulfamate was added, and the reaction was interrupted after about 20 min. The reaction mixture was poured into a bath containing 150 g of crushed ice and 150 mL of water, and the neutralization with cold KOH solution was immediately initiated during the cooling in the ice bath. When the neutralization approached its terminal point, the solution obtained a characteristic green-yellow color. The neutralization was then continued until the solution was weakly basic. The reaction mixture was evaporated in a rotavapor under vacuum to a completely dry powder. The dry powder was extracted with 10 mL of acetone; 100 mL of 2-propanol was added to the acetone solution, and the mixture was evaporated to dryness. Acetone dissipated first, and potassium dinitramide, having a low solubility in 2-propanol, precipitated. The crystals were filtered off and dried in a hot cabinet at 343 K (70 °C). The yield was 10.7 g KDN, which was 60% of theoretical yield. ADN can be made in the same way by starting out with $\text{H}_2\text{NSO}_3\text{NH}_4$ and neutralizing with NH_4OH . An alternate nitrating agent would be WFNA containing 28% by weight of pure SO_3 . KDN was recovered in yields between 50 and 70%.

Nitration of potassium sulfamate was carried out using a mixture of sulfuric and nitric acid at 243 K (−30 °C) using a sulfuric acid to nitric acid mol ratio of 1:3.5. Comparing the product yield by using ammonium sulfamate instead of potassium sulfamate, it was found that both the yield and purity of the product were better starting with potassium sulfamate [65].

Potassium sulfamate is one of the key precursors for ADN synthesis. Potassium sulfamate as a starting material was prepared in a lab scale from sulfamic acid solution with pH control by the addition of potassium hydroxide solution. The final pH of the solution was 7.5. Crystallization was induced by adding ethanol, methanol, acetone, and isopropanol and their mixtures [66]. Potassium sulfamate was then nitrated with nitric acid and neutralized with potassium hydroxide to make potassium dinitramide. Potassium dinitramide was converted to ADN. The effects of the quality of potassium sulfamate on the ADN yield and purity were evaluated by IR and UV analysis, X-ray diffraction (XRD), and DSC–thermogravimetric analysis (TGA). Potassium sulfamate made with acetone and/or a mixture of acetone and isopropanol, which was ground to 20 μm , showed the highest yield, which was more than 48%. The ADN purity obtained from the small-batch potassium sulfamate was better than that obtained from a commercial product. Crystallinity, porosity, and pore size of the lab-prepared

potassium sulfamate were compared with those of a commercial potassium sulfamate sample.

Crystallinity, porosity, and pore size are critical for potassium sulfamate to participate in the nitration reaction with rapid dissolution at low temperature because the reaction is reversible and the products can be destroyed in a strong acid; the reaction must be completed as quickly as possible. Five different solvents were evaluated for the synthesis of potassium sulfamate ($\text{H}_2\text{NSO}_3\text{K}$) to obtain different crystal properties [67]. The nitration of potassium sulfamate with WFNA was carried out at 238 K (-35°C). The nitration reaction with the gradual addition of potassium sulfamate powder was performed with very strong agitation to minimize extraction of by-products such as KHSO_4 . The neutralization with potassium hydroxide solution is exothermic and requires cooling. The metathetical reaction of KDN with ammonium sulfate was carried out in aqueous solutions. The solutions were concentrated, potassium sulfate was precipitated by the addition of acetone, and the ADN was extracted with ethyl acetate. The yield and purity of ADN depend on the quality of potassium sulfamate. Of the five potassium sulfamate samples, the maximum ADN yield (57.3%) was achieved using potassium sulfamate that had been obtained by precipitation by the addition of acetone. This ADN had a purity of 99.2%. Commercial potassium sulfamate did not give anywhere near such good results.

2.1.8 Starting with Nitramide

Nitramide (nitramine) is unstable and is not available commercially. It would have to be prepared by a separate process immediately prior to the synthesis of ADN. Nitration of nitramide leads to dinitraminic acid, which can be neutralized to form the ADN salt. ADN was prepared according to the method described by Bottaro et al. [27].

Separation of ADN from the reaction mix is difficult. To separate ADN from the reaction mixture obtained in the reaction between $\text{NO}_2\text{HS}_2\text{O}_7$ and nitramine in acetonitrile at 233 K and subsequent neutralization with aqueous ammonia, the following procedure was applied [28], consisting of separation of the unwanted solid that precipitated during the reaction, evaporation of the acetonitrile solution filtrate, extraction of the obtained solid with isopropanol, and evaporation of the isopropanol solution. Recrystallization from boiling ethyl acetate resulted in crude ADN with adhering ethyl acetate solvent. The purity of the products was examined using IR, TGA, differential thermal analysis (DTA), and elementary analysis. At best, the product contained 89% ADN with occluded ethyl acetate.

Initial attempts to nitrate nitramine H_2NNO_2 with a mixture of nitric acid and acetanhydride or dinitrogen pentoxide were unsuccessful. Treating nitramide with

a mixture of trifluoroacetic anhydride and nitric acid gave only very low yields of dinitramide. Thus, nitryl tetrafluoroborate, nitryl fluorosulfonate, nitryl hydrogen pyrosulfate, and nitryl pyrosulfate were tested as nitrating agents [68]. The best results were achieved with nitryl tetrafluoroborate and nitryl fluorosulfonate in acetonitrile at 253–273 K (–20 to 0 °C), which nitrated nitramine in only 5 min in very good yields. Extending the reaction time did not improve the yields. In methylene chloride or ethyl acetate as solvents instead of acetonitrile, the yield was substantially reduced. In hexane it was zero.

2.2 Production of Ammonium Dinitramide from Organic Starting Materials

An organic chemistry route prepares a doubly nitrated organic amine (alkyl-dinitramine) first followed by hydrolysis of the R–N bond and liberation of the dinitramide anion. Direct dinitration of primary amines is not always possible.

Most often, one of the hydrogen atoms on the amino group is protected by an inert group (inert to oxidation), which is later hydrolyzed to make space for the second nitro group. One should be concerned about safety when mixing any organic chemical with strong oxidizers such as dinitrogen pentoxide or nitronium salts. The reaction may turn into a hypergolic ignition. Many of the intermediates are potentially explosive.

2.2.1 Starting with Isocyanates.

In practice, synthesis started with aliphatic isocyanate reacting with methanol to form an alkylamino acid ester

could be nitrated in the first stage

hydrolyzed to the alkylmononitramine

converted to a salt, and nitrated in the second stage to form an alkyl-*N,N*-dinitramide [69].

KOH is shown as an example, but other strong bases can be used as well. This multistep route can be performed as a one-step reaction by reacting the aliphatic iso-

cyanate with stoichiometric quantities of NO_2BF_4 and HNO_3 in acetonitrile as the solvent. A facile conversion of aliphatic isocyanates to *N,N*-dinitramines is the treatment of isocyanates with a mixture of nitronium fluoroborate and nitric acid in acetonitrile, giving fair yields and simplifying the existing synthesis [18, 21].

The yield in this reaction was only 1–35% of theory, depending on the type of alkyl group in the isocyanate. The best yield (35%) was obtained with *n*-butyl isocyanate. The second-best yield (30%) was obtained with methyl isocyanate.

Another method for production of alkyl dinitramides is also an organic synthetic route. The amine in this case is derivatized with a group X such as in urea or bound to an electron-draining group such as $-\text{COOH}$ or $-\text{COOCH}_3$. This requires a stronger nitrating agent such as NO_2BF_4 or N_2O_5 .

Another method for producing ADN is to first prepare an *N*-(alkoxycarbonyl)-*N*-nitroamide compound. The *N*-(alkoxycarbonyl)-*N*-nitroamide may be formed by first mixing the corresponding alkyl carbamate with an anhydride of an alkyl carboxyl organic acid and then adding nitric acid to the reaction mixture [33, 70].

or

If a salt of the *N*-(alkoxycarbonyl)-*N*-nitroamide is to be formed first, a base (e.g., KOH) is added until the pH reaches about 7–10.

2.2.2 Starting with Urethanes

The reaction of *N,N*-dinitro urethanes, *N,N*-dinitrobenzamide, or *N,N*-dinitro-*p*-toluenesulfonamide with ammonia produced ADN in a yield of 44–85% [71].

For preparing KDN, 50 mL of acetonitrile was introduced into a 250-mL three-necked round-bottom flask equipped with an argon inlet, thermometer, stir bar, and gas outlet [72]. The flask and its contents were cooled to 235 K (–38 °C) in a liquid nitrogen/acetonitrile bath. To the cooled contents was then added 4.7 g (0.035 mol) of nitronium tetrafluoroborate. As soon as the temperature had re-equilibrated, 3.0 g (0.018 mol) of dipotassium nitrourethane was added in small portions such that the temperature did not exceed 238 K (–35 °C). The resulting suspension was stirred while allowing the temperature to rise to 254 K (–19 °C) until no further gas evolution was detected by visual inspection. The contents were then recooled to a temperature of

about 235 K (−38 °C), and a solution of 5.9 g (0.106 mol) KOH in 50 mL of ethanol was slowly added while monitoring the temperature such that it did not rise above 253 K (−20 °C). The contents of the reaction flask were then passed through a pad of silica gel on a glass frit, washed with several portions of ethyl acetate, and the combined filtrate was evaporated in vacuo. The resulting pale yellow solid, having a melting point of 381 K (108 °C), was pure potassium dinitramide (260 mg) as determined by ion chromatography.

2.2.3 Starting with Alkyl Carbamates

Ethyl or methyl carbamate can be nitrated using $\text{Ac}_2\text{O}/\text{HNO}_3$ to the corresponding mononitro compound [32].

followed by treatment with ammonia under anhydrous conditions to produce the ammonium salt of ethyl or methyl *N*-nitrocarbamate

which was further nitrated using nitronium salts or N_2O_5 and then treated with ammonia to give ADN, thus regenerating the starting compound $\text{RO}-\text{CO}-\text{NH}_2$ in the final step:

The first step of nitration was performed at <281 K (<8 °C), while the second step of nitration was performed in CH_2Cl_2 at 225 K (−48 °C) using N_2O_5 , and an overall yield of 70–76% was obtained, which is quite good.

In a method used by Chung and Sim [34, 35], nitration of the diethyl-4-azaheptanedioate using HNO_3 -trifluoroacetic anhydride (TFAA) gave *N*-nitro-4-azaheptanedioate

which was then base-treated in a retro-Michael reaction to give ethyl 3-nitraminopropanoate

The nitramino compound was treated with NO_2BF_4 at below 281 K (+8 °C) to give a dinitramino compound

and subsequently reacted with base to give dinitramide salts. The yield was 30% of theory.

Lukyanov et al. [73] developed a similar method for the synthesis of dinitramide salts in direct and retro-Michael-type reactions. $\text{HN}(\text{NO}_2)_2$ adds readily to $\text{CH}_2=\text{CHCOR}$ (**I**; $\text{R} = \text{H}, \text{Me}, \text{Ph}$) to give 53–85.5% $\text{RCOCH}_2\text{CH}_2\text{N}(\text{NO}_2)_2$ (**II**; same R), but did not react with $\text{CH}_2=\text{CHCN}$ or methyl acrylate **I** ($\text{R} = \text{OMe}$). Compound **II** ($\text{R} = \text{MeO}$) was prepared in four steps from $\text{MeO}_2\text{CCH}_2\text{CH}_2\text{NH}_2\cdot\text{HCl}$. Treating **II** ($\text{R} = \text{H}, \text{Me}, \text{Ph}, \text{MeO}$) with bases gave dinitramide salts in a 66–83% yield.

Instead of the ethyl ester of 4-azaheptanedioic acid, one can use the nitrile of the same acid. Such a method for preparation of ADN by nitration of bis(2-cyanoethyl)amine by nitric acid in acetanhydride, followed by decyanoethylation of 3-*N,N*-dinitraminopropanitrile by a strong base and further nitration with NO_2BF_4 , is shown below [35]. 3-*N*-Nitro-bis(2-cyanoethyl)amine could also be obtained by the oxidation of the corresponding *N*-nitroso compound:

The reaction was carried out at 381 K (108 °C). The yield was 60% of theory.

Ammonium *N*-nitro carbamate ethyl ester was synthesized from ethyl carbamate in $\text{HNO}_3/\text{H}_2\text{SO}_4$, and then, using N_2O_5 as the nitrating agent, ADN was prepared in a 70% yield [74]. It was recrystallized to yield a white hygroscopic powder with a melting point of 363 to 365 K (90 to 92 °C). Its structure was identified by elemental analysis, IR spectrum, and UV spectroscopy. The main factors such as reaction medium, reactant ratio, and reaction temperature were optimized.

2.2.4 Starting with Urea

Hatano et al. [30, 31, 75] invented a clean and safe method for the formation of ADN starting with the preparation of urea nitrate from urea and dilute nitric acid:

As the next step, nitrourea was made by reacting urea nitrate with sulfuric acid:

Dinitrourea (DNU) was made by reaction of nitrourea with a nitrating agent:

Neutralizing the formed DNU with ammonia gave ADN (and urea, which can be recycled):

The reaction was carried out at 233 K (−40 °C) in acetonitrile as a solvent. The yield of this method varied between 5 and 20% depending on the reaction temperature and reaction time. The yield in the last step of the preparation was ~15% based on nitrourea consumed. See also [76].

2.2.5 Starting with Urethane

A similar method for preparation of potassium dinitramide from urethane and acetyl nitrate proceeded as follows (although the resulting KDN product leaves a lot to be desired with respect to purity) [72]. In a jacketed 500-mL four-necked round-bottom flask equipped with a thermometer, top stirrer, and drying tube, 22.3 g (0.25 mol) of ethyl carbamate (also called urethane) was dissolved in 25 mL of dichloromethane (AR grade). The flask and its contents were immediately cooled to 263 K (−10 °C) with a refrigeration unit. To the cooled contents was then added an acetyl nitrate solution (prepared from 94.5 mL = 102 g = 1 mol of acetic anhydride and 35 mL = 51.8 g = 0.74 mol of 90% nitric acid), not allowing the temperature to exceed 298 K (25 °C). The addition took roughly 1 h, and after an additional hour at 263 K (−10 °C), the reaction was monitored by gas chromatography for the disappearance of urethane and subsequently the consumption of nitrourethane. When the reaction was judged to be complete, a strong solution of KOH in ethanol was added between 268 and 278 K (−5 and +5 °C). Enough of the base solution was added so that the pH was 8.18 (potentiometric). Following this addition, the reaction was stirred for 30 min and then filtered to remove the solids that had precipitated. The filter cake was washed with several portions of ethyl acetate, the filtrate and washings were combined, and the solvents were removed *in vacuo*. The yellow residue contained much acetic acid and acetic anhydride, which were removed by evaporation in a vacuum at ambient temperature at about 1 mm Hg. The resultant pasty solid was recrystallized several times from isopropanol to remove much of the potassium acetate and then from acetonitrile, yielding 4 g of potassium dinitramide, still contaminated with much potassium acetate. This sample was determined to be ~13% potassium dinitramide by ion chromatography.

An intermediate product prior to hydrolysis is *N,N*-dinitrourethane, $\text{C}_2\text{H}_5\text{OC}(=\text{O})\text{N}(\text{NO}_2)_2$, a precursor to ADN. In an effort to improve ADN yield,

its molecular structure was computed at the *ab initio* HF/6-31G level [77]. No structural evidence was found that *N,N*-dinitrourethane exists in the ionic form

The reaction of *N,N*-dinitrourethane with NH_3 passed through a transition state that is consistent with a concerted substitution in which $\text{N}^-(\text{NO}_2)_2$ is the leaving group.

2.2.6 Starting with Nitriles

In the synthesis of dinitramide from organic dinitramines of the type $\text{X}-\text{CH}_2-\text{CH}_2-\text{N}(\text{NO}_2)_2$, one will want to select alkyl rests where X consists of electron-withdrawing groups activating the α hydrogen atoms to nucleophilic attack, thus facilitating the creation of an anionic center in the β position to the dinitramine moiety [78]. The basic concepts have been tested in model reactions of β -substituted derivatives of *N*-alkyl-*N*-nitrotoluene sulfonamides with bases and were confirmed by the decyanoethylation of *N,N*-dinitro- β -aminopropionitrile.

Another method was developed to synthesize ADN from 3-aminopropionitrile [79]. The condensation and second nitration were identified as the critical steps of ADN synthesis.

Similarly, a method of ADN preparation from acrylonitrile or 2,2-dicyanoethylamine was developed, and the optimum reaction conditions were determined [80]. According to spectrophotometric data, decomposition of 2-(*N,N*-dinitroamino)propionitrile in aqueous buffer solutions (pH 9.5–11.5) at 290–318 K (17–45 °C) quantitatively yields dinitramide anion [81].

The process follows the general base catalysis pattern in terms of the E1cb mechanism, with deprotonation of the substrate as the rate-determining step. The reaction conforms to the Brønsted equation with a coefficient *b* close to unity.

2.3 Separation of Dinitramide Salts from Reaction Product Mixture

There are several ways the desired dinitramide salts can be separated from the mixture of unreacted reagents, products, and by-products. The cost of the separation process may determine the overall economy of ADN production. These separation methods can be used for dinitramidic acid and dinitramide salt solutions obtained from a variety of different processes, regardless of whether they started with inorganic or organic reactants.

2.3.1 Separation by Extraction

The dinitramide salt product may be extracted and separated from the by-product by solvent extraction. Typical solvents that may be used for solvent extraction include acetone, isopropanol, *t*-butanol, ethyl acetate, and tetrahydrofuran. The dinitramide salt can also be extracted by solutions of ammonia in chlorinated hydrocarbons such as $\text{CH}_3\text{Cl}_2\text{CHCl}_3$ and CCl_4 , as well as a mixture of ethyl acetate and *n*-butanol.

The solution containing the dinitramide salt product can then be evaporated to dryness in a rotavapor under vacuum.

The dried raw product residue may then be purified by redissolving and recrystallizing. For example, when *n*-butanol is used as the solvent, from about 5 mL to about 15 mL of *n*-butanol per gram of residue is used to dissolve the residue with heating to about 333–353 K (60–80 °C), after which the solution is cooled to about 258 K (–15 °C) and chloroform is added to precipitate the dinitramide salts as white crystals.

A useful method to separate impurities from the ADN product and to determine its purity is extraction with methyl isobutyl ketone [82]. The results showed that methyl isobutyl ketone is not only an effective solvent to separate the AN impurities but is also a good medium to chemically titrate the ADN. Both precision and accuracy of the purity analysis are good; the coefficient of variation is not more than 0.19%, and the relative deviation of the results to be determined with two methods is not more than 0.25%.

2.3.2 Separation by Precipitation

One separation method is to isolate the dinitramide in the form of a sparingly soluble salt that precipitates and can be separated by filtration and later converted to other dinitramide salts. The least soluble salt best suitable for this purpose seems to be guanylurea dinitramide (GUDN).

This method was patented [83, 84]. The addition of guanylurea gives a precipitate of GUDN. The precipitate is easily separated and can be used as starting material for preparation of other dinitramide salts, such as KDN and ADN. The guanylurea ion can be formed in situ in the process by cyanoguanidine that reacts and hydrolyzes within the reaction mixture.

Cyanoguanidine is not soluble and has to be added as a slurry. The remaining spent acid can be reprocessed for recovery of acid for preparation of a new nitrating acid mixture. This method allows the amount of waste to be reduced significantly, and partially spent acid can be recovered for preparing new nitrating acid. The main difference between the invention described in patent WO2005070823 and prior art is that the reaction mixture is not neutralized after a certain reaction time, but instead a cation is added, which forms an insoluble salt with the dinitramide anion that precipitates in the acidic reaction mixture.

In one example, a batch of 12 kg ammonium sulfamate was nitrated in a batch reactor with nitrating acid consisting of white fuming HNO_3 and 100% H_2SO_4 . The weight ratio of $\text{HNO}_3/\text{H}_2\text{SO}_4$ was 7 : 3, and the weight ratio of substrate/nitrating acid was about 1 : 5. The temperature was kept between 313 and 248 K (+40 and -25°C) during nitration, which lasted about 30 min. Then the reaction mixture was poured into a mixture of 6 kg cyanoguanidine in about 60 L of water. The aqueous mixture had a temperature of 288 K (15°C) and at this temperature was a slurry of partially dissolved and partially suspended cyanoguanidine. When the reaction mixture was mixed with the slurry, the temperature quickly rose to about 343 K (70°C), and after a short while a precipitate began to form. The mixture was cooled to 298 K (25°C), after which the precipitate of GUDN was filtered off and washed with water.

Part of the recovered GUDN was used for preparation of potassium dinitramide (KDN). A solution containing about 30 mass-% water, 60% ethanol, and 10% KOH was heated to about 323 K (50°C), and GUDN was dissolved in this solution during continued heating. After about 15 min, the solution contained 30 mass-% of dissolved GUDN, and cooling of the solution was started. KDN began to crystallize, and the mixture was further cooled to 288–293 K ($15\text{--}20^\circ\text{C}$), after which the crystallized KDN was filtered off and washed with ethanol. The mother liquor from crystallization contained guanylurea and was kept for recovery and later use in the process for precipitation of the dinitramide ion in nitration.

In a variation of this experiment, the experiment was repeated, with the difference that the reaction mixture from nitration was poured into an aqueous solution of guanylurea nitrate. The solution contained 15 mass-% of guanylurea nitrate and was cooled to about 285 K (12°C). The temperature rose when the reaction mixture was poured into the solution and the mixture was cooled to 298 K (25°C). Precipitation of GUDN started immediately, and the precipitate was filtered off and washed with water.

2.3.3 Separation by Adsorption

Conventional methods for separation of ADN from reactant mixtures and by-products involved precipitation, drying, extraction, and recrystallization from different solvents. This is a time-consuming and costly process. Adsorption techniques promise a more effective method of separation at a relatively lower cost in comparison to solvent extraction procedures for many materials, but the most economical method is precipitation. By using adsorption one will end up with ADN in a very dilute solution and getting rid of all water is very costly. ADN can be adsorbed on a variety of adsorbents such as molecular sieves, activated alumina, silica gel, and activated charcoal. The adsorbed ADN is then eluted with a suitable eluting solvent.

A different method (different from other patent applications) for separating the dinitramide salts is the passing of an aqueous solution of a mixture of salts formed in the neutralization through a column filled with an adsorbing agent, which selectively adsorbs the dinitramide salt [36]. The adsorbing agent can be activated carbon [85],

powdered activated charcoal (PAC) or granular activated charcoal (GAC) [58], silica gel, or zeolites. The adsorption of ADN from aqueous solutions on GAC follows monolayer adsorption because the data fit in a Langmuir isotherm. The dinitramide salt can be eluted from the adsorbing agent with hot water and/or a polar organic solvent such as acetone, acetonitrile, 2-propanol, or other lower alcohols.

Contamination by a large number of inorganic salt by-products is inevitable in the synthesis of ADN by the mixed-acid method. ADN can be effectively separated and purified by adsorption with activated charcoal [86]. Different kinds of activated charcoal, adsorption solvent, and desorption solvent, as well as concentration and method of adsorption were tested, and the optimum operating conditions were determined. Pure ADN with greater than 99.5% assay was prepared by this method.

2.4 Purification of Ammonium Dinitramide

ADN that has been prepared by a variety of methods can be purified by a combination of recrystallization and adsorption. Several purification processes for precipitated ADN particles have been evaluated, including repetition extraction, activated carbon adsorption, and low-temperature extraction [87, 88]. The purifying methods helped improve the chemical purity as analyzed by Fourier-transform infrared (FTIR) spectroscopy and UV-visible spectroscopy in addition to ion chromatography (IC) analyses. Among the purification processes, adsorption was found to be the best method, resulting in a final purity of 99.8% based on analysis by IC.

2.4.1 Cation Conversion Among Dinitramide Salts

Once one dinitramide salt is obtained, and the dinitramide salt of a different base is desired, the cation can be exchanged by metathetical reactions, e.g.

In the case of the reaction above, ammonia can be removed by sparging, and the equilibrium will be shifted to the right.

Dinitramide salts have good solubility in several organic solvents. Selective extraction will allow the separation of dinitramide salts from reaction mixtures and purification of the salts by recrystallization.

ADN can be prepared from KDN by mixing an aqueous solution of KDN with an aqueous solution of $(\text{NH}_4)_2\text{SO}_4$, whereby a white precipitate of K_2SO_4 is formed. 2-propanol is added to the mixture, and the K_2SO_4 precipitate is separated. The decanted solution is evaporated until ADN precipitates. If necessary, the product from the evaporation can be redissolved in 2-propanol and poured into a non-polar solvent, e.g., petroleum ether, whereby a purified grade of ADN precipitates and can be separated [36]. ADN can also be prepared from KDN by mixing KDN and $(\text{NH}_4)_2\text{SO}_4$

in 2-propanol and heating the mixture, and optionally reflux-boiling the mixture until the ammonium sulfate has dissolved. The solution is then cooled, whereby K_2SO_4 precipitates and can be separated. The remaining solution is concentrated by evaporation, and the concentrate is poured into a non-polar solvent, e.g., petroleum ether. A pure form of ADN precipitates and can be separated.

Another method to convert one dinitramide salt into another is by ion exchange on an ion exchange resin.

There are several patents in the literature describing the preparation of various dinitramide salts of less common bases, starting with either ADN or KDN. Of particular interest are the dinitramide salts of guanidine, aminoguanidine, triaminoguanidine, guanylurea, and other nitrogen-rich bases that can be used as ingredients in gas generators for airbag inflation (see *Encyclopedia of Liquid Fuels*, chapter “Amides”).

A simple method for converting ADN or KDN into guanidinium dinitramide or GUDN by metathetical reaction is described in [89]. This is done by mixing a concentrated aqueous solution of ADN with a concentrated aqueous solution of an organic ammonium salt whose anion is either OH^- or CO_3^{2-} , which is capable of taking up a proton from the ammonium ion of ADN and forming an ammonium salt. Ammonia (and possibly carbon dioxide) is driven off from the solution, as well as a certain amount of water to maintain a concentrated solution. The organic dinitramide salt is then precipitated by cooling the solution and is recrystallized if needed.

2.5 Morphology and Particle Shapes of Ammonium Dinitramide

The as-produced ADN is in crystalline form, and the particle size and shape depend on the rate of cooldown during crystallization. This may not be the optimum particle size and shape for incorporating ADN in solid propellants. ADN normally grows in long, flat blades from a variety of organic solvents. However, these shapes have a large length/diameter ratio and do not allow a dense, cohesive packing in a composite solid propellant. Friction between the flat crystals does not allow the powder to be poured out of containers as a free-flowing powder. Alterations of crystal shape can be achieved by changing the conditions of crystallization from either a melt or a solution. This can be done by changing the temperature, rate of cooling, pressure, solvent, or supersaturation and seed crystals. Recrystallization is necessary to improve the physical properties of ADN, its burning characteristics, and its chemical purity.

2.5.1 Recrystallization of Ammonium Dinitramide Without Additives

The simplest approach would be to recrystallize the salt and change the solvent and the rate of cooling in order to achieve ADN crystals with a more favorable aspect ratio. In one such investigation, 1-propanol and 1-octanol were used as candidate solvents [90]. Cooling crystallization experiments were carried out under different

process conditions using 1-propanol and 1-octanol as solvents to see how they influenced the crystal morphology [91]. Supersaturation during the process was determined, and the crystal shapes and the thermal behavior were characterized. The experimental work was supplemented by computer simulations examining the vacuum morphologies. The relevant growth-faces were identified by comparing the calculated morphologies to the crystals collected from the crystallization dish. Force-field methods were used to determine the influence of the polarity of the solvent and the interaction energies of the solvents with the ammonium ion, the dinitramide ion, and the crystal faces. The crystal growth behavior was described step by step while taking the molecular structure of the crystal faces into account. From the natural cooling experiments, 1-propanol turned out to be the most promising solvent for obtaining crystals with a low aspect ratio. The crystallization of ADN from 1-octanol resulted in differently shaped crystals depending on the level of supersaturation during the process. At low supersaturations, plate-shaped crystals with a compact base area were obtained. A key parameter during particle formation by crystallization is the supersaturation as the driving force for kinetic processes like nucleation and growth. Therefore, its control is indispensable for monitoring and optimizing ongoing crystallization processes to achieve reproducibility and product quality. Before a supersaturation-controlled crystallization process can be run, a suitable method for the inline real-time measurement of the concentration has to be evaluated for the material system. High supersaturations lead to rod-shaped crystals but with a rough surface [92, 93]. Plate-shaped crystals resulted from all crystallization experiments with 1-propanol as solvent. Different cooling rates did not change the morphology, and that was recrystallized from three different alcohols was thoroughly characterized by scanning electron microscope (SEM) imagery, XRD, DSC, and TGA [90].

Repeated recrystallization of ADN may actually increase its AN content instead of purifying the material. ADN received from Eurenco Bofors in Sweden with a purity >99% contained the following impurities: K^+ , guanidinium⁺, NO_3^- , H_2O , Si. Instead of recrystallization, the users decided on *in situ* filtering of the finished product (FLP-106) to remove insoluble contaminants that might clog the rocket injectors.

The influence of solvents on ADN crystal shapes and morphology was investigated using a combined experimental and molecular dynamics simulation approach [94]. Scanning electron microscopy showed that ADN recrystallized from acetone, propanol, dimethyl sulfoxide, or ethanol exhibited a lamellar structure, in contrast to the polyhedron structure obtained with isopropanol/NaF. XRD scans revealed that ADN crystals are mainly composed of six crystal faces (010, 011, 110, 100, 121, 031), and acetone, propanol, dimethyl sulfoxide, and ethanol resulted in crystals in which growth was preferentially at face (100). Molecular dynamics computations indicated that the accessible surfaces and lattice energy vary with the crystal faces. The interaction energy between solutions and crystal faces was dependent on both crystal faces and solution components, as was the attachment energy. Based on XRD data, a larger relative standard deviation of the growth rate

of the crystal faces resulted in a lamellar structure, while a smaller relative standard deviation gave more homogeneous growth rates that resulted in polyhedron crystals.

The solubilities of ADN in *n*-butanol, isopropanol, and mixtures of water and isopropanol (volume ratios of 1:10 and 1:6) were measured by a dynamic method, and the solubility data were fitted by the Apelblat equation and λh equation, respectively [95]. The effects of stirring speed and cooling rate on the metastable zone width of ADN in *n*-butanol and isopropanol and the effects of different supersaturation on the induction period were investigated. The results showed that the Apelblat equation and the λh equation can describe the solubility of ADN accurately. The width of the crystalline metastable zone narrows with a decrease of the cooling rate and an increase of the stirring speed. The crystallization induction period shortens with an increase of supersaturation. Using the self-consistent Nyvlt equation and three-dimensional (3D) nucleation theory, combined with the metastable zone width and induction period data, the nucleation order m was calculated to be about 4, and the solid-liquid interfacial tensions of ADN in *n*-butanol and isopropanol were 0.235 and 0.191 mJ/m² for homogeneous nucleation, and 0.070 and 0.067 mJ/m² for heterogeneous nucleation, respectively.

A solvent/antisolvent method can be used for recrystallizing ADN and changing the morphology of the rapidly precipitated crystals [96].

2.5.2 Recrystallization of Ammonium Dinitramide with Additives

Another promising approach is to recrystallize the material from a solution in the presence of surfactants or additives. Better yet, instead of recrystallizing (unless it is done for purification), one can apply the additives when ADN is first made and the precipitates from the reaction mix. Some additives act as contaminants, inhibiting growth through specific surfaces of a crystal, thereby changing the crystal habit and its morphology. Such additives can also stabilize polymorphs or can inhibit nucleation of polymorphs. The crystal habit modifiers must be effective in small amounts, which minimizes the risk of contaminating the crystals, modifying other critical properties of the ADN crystals.

Attempts have been made to modify the habit of crystalline ADN from blades to short prisms by controlling its growth behavior in isobutanol or methyl acetate using tailor-made additives [97]. A series of long-chain alkyl diamines, amino acids, and aromatic diamines were tested as additives. The strategy was unsuccessful, but in the process, a new compound, butanediammonium dinitramide (BDDN), was isolated and characterized. BDDN has a similar space group to ADN, and its habit is sensitive to growth conditions, crystallizing in short prisms and two types of blades. For these reasons, the growth behavior, surface, and packing structure of BDDN were analyzed in the hope that these might give some clues to ADN habit modification. It was also observed that ADN can have a “twinned prism” habit. These crystals possess a much lower aspect ratio than the blades and exhibit an unusual threefold twinning. To com-

plement the study, a texture analysis study of ADN spherulites (small spheres made up of millimeter-to-micron-sized ADN crystallites) was made. Using XRD and mathematical analysis, it was determined that the crystallites in spherulites do not adopt any obvious preferred orientation.

A French patent contains a long list of calcium or magnesium salts of carboxylic acids as modifiers for ADN crystallization [98–100]. Among others, a mixture of calcium nitrate and finely divided calcium carbonate is said to improve the crystal shape. Crystals prepared in this manner were also less hygroscopic than normal ADN. As solvents, mixtures of ethanol and methanol were used. Calcium and magnesium salts that are soluble in ethanol and methanol were recommended as growth modifiers. The anions of the salts did not disturb the crystal growth of ADN. Different temperature profiles (linear, stepped profiles) were tested. The aspect ratio of crystals could be reduced from 10 (crude ADN) to 1.5–5. The modified crystals were used in an energetic formulation containing ADN, hexogen, aluminum, and a binder material. The processability of the formulation was improved by reducing the viscosity from 1020 Pa · s (crude ADN) to 560 Pa · s (improved crystals).

Crystallization by spontaneous nucleation and crystal growth can be used to purify ADN, starting from a saturated solution and with cooling in the presence of a protic solvent with a viscosity of $\eta = 250$ cPs, especially 450–550 cPs [101]. A preferred solvent is a mixture of glycerol and 1,4-butanediol. The resulting crystals have a median diameter of $\sim 100 \mu\text{m}$.

2.5.3 Prilling of Ammonium Dinitramide

Prilling (converting irregularly shaped crystals to spherical particles or beads) can be done by spraying molten ADN into a suspension with an inert liquid or allowing it to free-fall in a tall prilling tower in dry air.

In a prilling tower, needle-shaped ADN powder is melted, and it cools when falling through the tower against an updraft of cold air. This enables production of ADN prills of good quality. However, the particle size cannot be altered. There are concerns about the safety of the process because of the high temperature in the prill tower.

ADN, as manufactured, is difficult to formulate since it forms crystals of excessive length, making it process poorly in propellant formulations, raising their viscosity and making them difficult to cast. The cooling of molten droplets to form tiny spheres may be used to manufacture the ADN in a more suitable form for processing, but prilling involves melting the ADN and then stirring or spraying. Stabilizers are not needed as long as ADN is not kept in the molten state for prolonged time. Stabilizers are not typically used when prilling is done quickly. Particulate oxidizer requirements have led to the demand for spherical particles with defined particle sizes for composite solid propellants. We want to create mixtures of liquid polymer binder systems with a high solids content of particulate energetic materials (oxidizers and energetic additives). Spherical particles generally can be formed via the dispersion of a liquid phase,

which then becomes droplets, in a continuous phase. Because the spherical shape and the particle size are important particle properties, it is, in the case of both AN and ADN, more convenient to work with melts than with solutions. Very uniform packing and good solids loading densities are achieved with spherical particles prepared by melting ADN and dripping the melt into a cooled and rapidly stirred bath of an inert fluid in which ADN is not soluble (“prilling in suspension”). The melt droplets solidify in a spherical shape (prilled shape). The ADN prills are reported to possess higher thermal stability and are less sensitive than the crystalline ADN resulting from the synthesis and the use of bimodal mixtures of ADN. Prills of varying particle sizes in a propellant composition are expected to offer a higher solids loading and a high theoretical maximum density. Figure 4 shows a comparison of as-crystallized and prilled ADN particles.

Figure 4: Comparison of prilled and as-crystallized ADN. (Reprinted from [102], by permission from © 2008 Springer Nature; permission conveyed through Copyright Clearance Center Inc.)

The particle shape and particle size of as-synthesized ADN are not uniform, and particles tend to agglomerate. In order to have a reproducible burning rate, it is necessary to modify the particle shape of the initial material to form particles with a defined ratio of surface/volume and a predetermined mean particle size and particle size distribution. It is best to form spherical particles. Spheres can be shaped in a two-phase system. In this case, the molten ADN is dispersed in a continuous phase, which is not miscible with ADN [103]. The surface tension and interfacial tension cause the molten droplets to assume a spherical shape. The solidification of the molten droplets to spherical prills takes place during the cooldown to a temperature below the melting point of ADN. With proper choice of suitable oil bath fluids and spray nozzles and optimization of the process parameters, spherical ADN particles with mean particle sizes ranging from 5 to 800 μm can be manufactured reproducibly.

Other publications give mean particle sizes ranging from 10 to 600 μm [104, 105]. The prilling process consists of two stages: In the first stage, molten ADN is dispersed in a continuous phase in which ADN is insoluble. The droplet size produced can

be controlled by varying the amount of agitation. The influence of the different process parameters, such as dispersion rate, dispersion power, emulsification time, influence of emulsifying agents, and the rheological behavior of the continuous phase, has been studied to optimize the process. In the second stage of the process, crystallization of the emulsified ADN droplets to spherical, solid particles is obtained by quickly reducing the temperature of the system. This process gives spherical ADN particles with mean sizes ranging from 10 to 600 μm . The ADN concentration in the stirred hot-oil bath was varied from 5 to 25 mass-%. Fumed silicon dioxide was used as a protective colloid to promote emulsification. After crystallization and filtration, the particles were washed and dried. The product quality of the crystallized ADN was determined using various analysis techniques, including DSC, IR spectroscopy, IC, and laser light diffraction spectrometry.

The Fraunhofer Institute of Chemical Technology (ICT) in Germany has studied several prilling processes and characterized the spherical particles, as well as made comparisons to prilled AN. Melt spraying is preferred because molten AN and ADN droplets usually nearly keep their shape and size while solidifying, whereas droplets of a solution always have to dispose the solvent to become solid particles. These oxidizer melts can be dispersed in a gaseous or liquid phase. Depending on the crystallization kinetics (nucleation and crystal growth) of the molten droplets, two possible processes can occur: In the case of AN, the recrystallization is fast enough to enable a spray crystallization process by using a prilling tower. ADN, unfortunately, has inhibited and delayed crystallization properties. This makes it necessary to give the molten droplets more time and encouragement to nucleate to complete their phase transformation into solid particles. Therefore, a liquid-liquid emulsion crystallization process was adapted at ICT to the special properties of ADN [106–111].

This process can be modified such that additives (stabilizers, combustion modifiers, and/or energy carriers) are trapped deliberately in the solidifying ADN droplets, giving them more favorable burn characteristics in a solid propellant [112].

Very small droplets in the size range of 40 μm are formed if the melt/oil mixture is agitated with ultrasonic agitation [113]. However, one must consider that ultrasound may also induce decomposition of ADN [114]. The viscosity of the non-polar fluid dispersion bath can be adjusted to obtain the desired particle size. Another method would be to spray the molten salt into a prilling tower and let it solidify during free fall. Doing this in an evacuated tower or operating at lower pressure will reduce the porosity of the solidified prills. Packing densities better than hexagonal dense packing of spheres are possible with multimodal particle size distribution of ADN.

While porosity of the prills may be undesirable for solid propellants, it may be acceptable for prills that are intended to be filled with organic oils and used as explosives [115]. One can also coat the particles with HTPB monomer and plasticizers in preparation for their being embedded in a matrix of polymerized HTPB [116]. The desired aspect ratio of ADN crystals may be achieved by adding surfactants to the solution from which the ADN crystallizes. The melt method of prilling ADN using HTPB/

dioctyl adipate/dioctyl sebacate as the liquid medium has been optimized to produce good-quality spherical ADN particles. The parameters studied and optimized include stirring speed, viscosity and components of the liquid medium, effect of additives, and the design of stirrers and reactors. Water is the possible cause of particle agglomeration (highly undesirable). Particles in the size range of 25–250 μm could be obtained by adjustment of the liquid medium and stirring speed.

Prilling by spraying droplets of molten salts into a stirred pool of an inert, cool liquid in which the droplets can assume a spherical shape before they solidify can be applied to a wide range of energetic materials, including ADN and AN [117, 118].

The particle size of prilled ADN is determined by the surface tension of the molten ADN as it sprays out into the stirred fluid bath, and the droplets are suspended in the fluid until they solidify. The surface tension and the wetting angles of molten ADN were measured in order to select proper equipment (nozzles, agitator paddles, heaters) and materials of construction in contact with ADN [119]. It is difficult to get the dispersion of molten ADN droplets to solidify before the droplets stick together and re-agglomerate. Because the melt has a tendency to supercool, seed crystals may be required to induce solidification.

Up to the year 2000, the production of spherical ADN particles (so-called ADN prills) at ICT was a batch process, using the emulsion crystallization technique. The next step was to develop a continuously working ADN-prilling process. The advantages of a continuous process for ADN are the following:

- less thermal stress, as the ADN remains in the heating zone only for a very short time
- a safer process because there is less ADN in the heating zone
- the possibility to scale up the process

It was shown that it is possible to generate spherical and particles with an adequate particle size distribution by combining the micro reaction technique and the ADN emulsion crystallization process [106, 120, 121].

To obtain ADN particles in a spherical form, decane is used as an antisolvent (continuous phase of the emulsion). A surfactant is also necessary to lower the surface tension, in this case the interfacial tension, and to obtain smaller particle size. An anticaking agent is needed to reduce unwanted agglomeration. A suspension of these solids is fed to a heating zone microreactor, where it emerges as a liquid-liquid emulsion that is fed to the stirred cooling tank, from which ADN prills crystallize on cooling [122]. Among the parameters to be optimized are the flow rate, reactor diameter, and reactor temperature. Reactor temperatures below 393 K (120 °C) may lead to clogging, while reactor temperatures above 398 K (125 °C) may cause premature ADN decomposition and explosions.

Shortly after ADN first became commercially available, the U.S. Navy at Naval Air Weapons Station China Lake in California conducted an evaluation of samples procured from two different domestic sources [123]. Most of the ADN samples were

very pure, containing only 0.05–0.55% AN. Occasionally, a trace of ammonium nitrourethane (one of the starting reactants for making ADN) was detected. One of the samples contained 0.55% nitrate ion and 0.52% ammonium nitrourethane. For preparing small (2–3 g) batches of prilled ADN, the temperature of the melt had to be carefully controlled and kept below 383 K (110 °C), and the time spent at this temperature was limited to 15 min. This very much limits the size of a batch process. The addition of 0.3% hexamethylenetetramine (“hexamine”) stabilized the ADN. A vacuum thermal stability test of the product (4 h at 371 K [98 °C]) showed substantial improvement of ADN stability because of the addition of hexamine when compared to unstabilized ADN. If the temperature was allowed to exceed 393 K (120 °C), the material started gassing, and the prills became porous.

Thiokol developed a prilling process involving the addition of additives before prilling to overcome potential shortcomings of ADN when compared to AP [124]. In this process, solid granular ADN is introduced into the top of a melting column and is allowed to melt to form pre-prills while passing through a hot zone in the prilling column. The pre-prills are allowed to “spheridize” in the presence of an upwardly flowing inert, immiscible fluid, which partially counteracts the gravity of the ADN in the prilling column. The flow rate is selected so as not to carry the ADN out of the top of the prilling column. The rate of “spheridization” can be accelerated by providing additional cooling to the cooling zone in the prilling column where the spherular granules leave the apparatus [125–128].

ADN that was produced by Bofors in Sweden was evaluated at Naval Air Weapons Station China Lake [129]. This ADN was composed of either plate-like or needle-like crystals and was of an excellent chemical purity (as analyzed by IC). The IC analysis showed it to be at least 99% pure, with 0.13% nitrate and 0.03% sulfate and no detectable nitrite. The Chemical Systems Division of United Technologies had converted some of the Swedish ADN into prills by a process that involved molten ADN and immiscible mineral oil emulsion technology. This patented process [130, 131] minimizes the time during which the ADN is in the molten state by feeding the coarse ADN at a controlled continuous rate into a heating chamber, melting the ADN, and immediately spraying the melted ADN continuously into a non-solvent cooling fluid maintained at a temperature below the temperature of solidification of the ADN. The cooling fluid bath is agitated to promote the formation of droplets of controlled size, which solidify in the cooling fluid to produce substantially spherical ADN in a narrow particle size distribution.

The quality of prilled ADN depends on the immiscible liquid organic fluid, dispersant, surface active agents, and stabilizers, and on the methods of selecting these auxiliary agents. Hygroscopicity, particle size distribution, impact sensitivity, friction sensitivity, and surface structure of prilled ADN were studied. Results showed that prilled ADN has lower hygroscopicity and sensitivity than flake or needle ADN. Prilled ADN with particle sizes from 5 to 800 μm can be produced in this way [132, 133]. Crystal shapes of many solid propellant oxidizers need to be changed to decrease sensitiv-

ity, improve mechanical properties, and obtain optimum performance from oxidizers such as ADN and HNF [134].

The emulsion crystallization process involves the melting of ADN in paraffin oil maintained above the melting temperature of ADN. The hot paraffin oil along with the molten ADN was mechanically stirred using a propeller stirrer (M) at 400–500 rpm to get uniform spherical droplets of ADN, followed by cooling of the paraffin oil to room temperature and isolation of spherical grains by washing with a solvent. In a typical experiment, 20 g of dried ADN was slowly introduced into hot paraffin oil maintained at 365–366 K (92–93 °C) in a jacketed reactor, along with 0.1% of fumed silica (Cab-O-Sil) as a protective colloid to prevent particle-particle adhesion [58, 135, 136]. This process enables production of spherical grains of ADN with a mean particle size of 100–500 μm .

Processing ADN into solid propellant mixes has been a significant challenge because it emerges from the basic manufacturing process as hard, angular crystals that do not lend themselves to being mixed into high-solid-loading solid propellants. Even after grinding, the smaller, but still hard, crystalline material has sharp edges and does not process very well. That is one reason why prilling efforts continued at several organizations even long after this material had been discovered.

The ADN used in Sweden was procured from Eurenco Bofors in Sweden, which has been producing dinitramides on a pilot plant scale since 1996. The particle shape of ADN as received from Eurenco is needle shaped and thus not suitable for solid propellant formulation. At FOI in Sweden, a method to produce spherical ADN particles was therefore developed [11, 12]. The prills are produced by spraying molten ADN through a nozzle. In the nozzle, the molten ADN is atomized to form droplets, which then solidify to the desired prills seen in Figure 5 and 6.

Figure 5: Prilled ADN. (Photo courtesy of FOI Sweden, reprinted with permission.)

Figure 6: Scanning electron microscope image of prilled ADN. (Photo courtesy of FOI Sweden, reprinted with permission.)

The particle size can be controlled to some extent by varying the spray nozzle size and pressure. Typical particle size distributions for the fine and coarse prills produced are given in Table 3 and illustrated in Figure 7 from [14].

Table 3: Typical particle size distributions of prilled ADN.

Grade	d10 (µm)	d50 (µm)	d90 (µm)
Fine	30	60	120
Coarse	30	200	400

Data source: Wingborg et al. [11]

As a result of the heating and prilling, the nitrate contamination in ADN increased from 0.03 to 0.08 mass-%, which is undesirable and lowers the melting point from 366.3 to 365.6 K (93.2 to 92.5 °C). Particle density drops from 1.81 to 1.79 g/cm³, but tap density is improved from 0.86 to 1.11 g/cm³.

Johansson et al. produced spherical ADN particles using a spray prilling process [137]. The ADN was first melted and then atomized by spraying it through a nozzle by the use of pressurized nitrogen into a cold bath of liquid nitrogen. The relative humidity in the working chamber had to be kept very low. The particle size can be varied by using nozzles with different diameters. The particle size distribution obtained with two different nozzles is shown in Figure 8.

Figure 7: Particle size distribution of fine (upper graph) and coarse (lower graph) ADN prills. Two measurements on each grade. (Reproduced and modified from [14]. Creative Commons Attribution-NonCommercial 4.0 International, CC BY-NC 4.0)

Figure 8: Particle size distribution of ADN prills obtained with nozzles of two different sizes. (Reproduced/Printed/Used and modified from [137] with permission obtained from FOI Sweden 9-Jun-2020)

The density of spray-prilled ADN spherules was in good agreement with its theoretical value (1.818 g/cm^3). This showed that the spray-prilled ADN particles were homogeneous, without any voids. The spray process may actually increase the purity of ADN by removing volatile impurities. Some initial results indicated that freshly spray-prilled ADN may not be completely morphologically stable. After storage for some days, it seems that the surface structure of spray-prilled ADN becomes more irregular. This behavior was more pronounced when the prills were stored at higher humidity. See also reference [138].

ADN that is intended for melt casting (also in mixtures with aluminum powder) can be stabilized by the addition of 1% MgO [139].

Other stabilizing additives can be co-dispersed with the molten ADN and will be embedded in the prilled spherules [112, 140]. This method enables the homogeneous distribution of additives in ADN particles with minimal adverse thermal effects.

The application of ADN in solid propellant formulations requires spherical particles of at least two different particle sizes, typically a coarse particle-size fraction in the range of 200–250 μm and a medium particle-size fraction in the range of 30–60 μm . In addition, a fine fraction of about 5 μm would be desirable for multimodal particle-size distribution. Several process variables of the emulsion crystallization process for ADN, the so-called ADN-prilling process, were modified to achieve these particle-size distributions [141]. By varying process fluids, additives, stirring energy, and recrystallization behavior, it was possible to generate medium-sized ADN prills with a mean particle size of 50 μm and coarse ADN prills of approximately 200 μm in technical-scale batches.

The possible particle size range for producing ADN prills could be expanded down to 35 μm and up to 320 μm [142]. Demonstrated particle size ranges for reproducible kilogram-scale production batches were as follows:

- medium-fine ADN prills: 50–60 μm
- coarse ADN prills: 150–250 μm

These ADN prills will be tested in bimodal oxidizer particle size propellant formulations. Important parameters to investigate are the casting viscosity and mechanical stability of the formulations. Another investigation is the dependency of the burn rate on the particle size of ADN prills. The large ADN prills generated by targeted seeding showed an inner layer structure.

The ADN-prilling process by emulsion crystallization can be scaled up to the multiple-kilogram production level [143].

The particle size, the outer shape, and the surface area of ADN prills are the most important particle properties of ADN prills formed by the emulsion crystallization process. If necessary, the surface may be additionally refined by particle-coating technologies. Besides the external appearance, the internal characteristics of particles are of considerable importance. Defects, pores, or impurities have unfavorable effects on the particle's properties, e.g., increased sensitivity, whereas the crystal structure of

particulate energetic materials may affect the mechanical properties of the particles. It was found that the crystal formations inside the and prills have a layered structure or at least a preferential direction [144, 145]. This phenomenon was investigated using XRD, microscopy, and measuring of the mechanical strength of the particles.

ADN prills are producible in the particle-size range of 40–200 μm . If necessary, the ADN prills can be refined by fluidized bed technology, such as by creating coating layers with improved bonding behavior to solid propellant binder systems. This leads to comparatively better mechanical properties of propellants made with thusly coated ADN prills than with uncoated ADN prills. The crystal structure was investigated using XRD, and the thermal stability was determined by vacuum stability tests and mass-loss measurements [146].

Spherical ADN particles (ADN prills) can be produced continuously in microfluidic droplet generators that promise improved size and dispersity control of the prills and open new possibilities to explore the influence of additives on the properties of ADN [147]. This process can minimize the thermal decomposition of ADN during the prilling process by heating up only small amounts that are used immediately for the process. Microfluidic droplet generators using parallelized microchannels offer the potential of scaling up the process.

Prilled ADN can be made by an emulsion crystallization process that allows the operator to control the morphology of the product [148].

2.5.4 Grinding of Ammonium Dinitramide Particles

In attempting higher burning rates, it is common practice to work with smaller and smaller oxidizer particle sizes. Grinding can achieve smaller particle sizes than prilling from the melt. With the high friction sensitivity of ADN, it is not a good idea to comminute ADN by grinding, unless it is done in a suspension with an inert solvent. Ultrafine, potentially explosive particles can be produced by a bead-milling technology. Micro-scaled ADN was obtained by milling of a non-aqueous ADN/decane suspension with a diving basket mill, filled with ceramic beads. Particles with a mean size of 2.06 μm could be successfully produced in technical-scale batches [149].

2.6 Coatings for Ammonium Dinitramide Particles

Several coating methods have been developed and tested for ADN to reduce its sensitivity to moisture and improve the wettability by binders in solid propellants. Without any anti-caking agent, the prilled ADN cakes after a short time of storage, even in dry conditions. Sometimes the coating process is combined with the incorporation of other additives into the ADN particles.

An improved coating method coats the ADN prills first with wax and then with an amine resin [150]. Coating of ADN favorably reduced its friction and electrostatic

discharge (ESD) sensitivity. Prilled ADN was coated with polymeric materials, and the extent of moisture absorption at different relative humidities was measured [58]. Ethyl cellulose (EC) and poly(methyl methacrylate) (PMMA) dissolved in methylene chloride were used as coating materials. The coated ADN granules were then evaluated for their moisture pickup at relative humidities of 62 and 74%. Varying amounts of coating material (0.5–2%) showed a decrease in the moisture uptake of ADN. For ADN coated with 2% EC, the moisture uptake at 60 min was 4.43%. The moisture absorption profile of ADN coated with PMMA showed a similar trend as that observed for ADN coated with EC. At 60 min at 74% relative humidity, the moisture uptake was 7.6% for uncoated and 4.03% for ADN coated with 2% PMMA. ADN samples coated with PMMA showed lower moisture uptake than those coated with EC.

A combination of additives and coatings can improve the thermal stability and safety property of the oxidizer and the solid propellants made therefrom [151]. The particles are suspended in a fluidized bed, and the coating solution is sprayed on and must dry quickly before the particles agglomerate and stick together [152]. Particles with a mean size of 120 μm can be coated separately and with uniformly thin layers. Supercritical solvents can be used for coating and microencapsulation of energetic materials such as ADN. With this method, drops or fine particles of a solution of the coating agent in a supercritical fluid are sprayed onto <100- μm particles of the substrate in a fluidized bed [153, 154].

A potential drawback of ADN is the lack of compatibility with common curing agents used in most binder systems. This incompatibility can be overcome by coating the ADN particles. At ICT, a fluidized bed technology was used for the processing of hygroscopic and explosive granular materials [155, 156]. Different polymeric coating materials have been tested to find one suitable for application in a fluidized bed. The properties of the coated ADN particles were characterized by microscopy, particle-size distribution, specific surface area, and crushing strength of individual particles. ADN prills can be coated without agglomeration and with uniformly thin layers. The mechanical strength of particles was improved by the coating. The compatibility of coated and uncoated ADN prills and isocyanate containing binder systems was investigated by microcalorimetric measurements and vacuum stability tests [157]. It was shown that the compatibility could be improved by coating the ADN prills with polyacrylates, HTPB, or glycidyl azide polymer (GAP).

The fluidized bed technology allows production of composite particles consisting of layers of different energetic materials. Three different examples of layered energetic composite particles were demonstrated [158]:

1. ADN prills (spherical ADN particles) were coated with thin layers of GAP, which increased the compatibility with isocyanate-containing binder systems and the mechanical stability.
2. Spherical AN particles could be coated with UV-curing polymers, which led to mechanically stable core-shell structures.

3. Composites of mostly HMX (approximately 90 mass-%) and small amounts of FOX-7 or FOX-12 resulted in reduced friction sensitivity of the whole composites.

Prilled ADN was coated with polyurethane (PU) to reduce its hygroscopicity [159]. The surface appearance and hygroscopicity of ADN after coating were analyzed by SEM and gravimetry. When coated ADN was exposed in air for 30 d with relative humidity less than 60%, the weight gain of coated ADN was only 0.136% and did not increase with extension of the exposure time. Differential thermal analysis and mechanical sensitivity tests showed that PU had little effect on the melting point, decomposition peak temperature, or enthalpy of coated ADN, but the friction and impact sensitivity of ADN increased. The drop height for the impact sensitivity 50% point decreased from 30.5 to 27.8 cm.

ADN in its generic form has long needle-shaped crystals, which hinders higher solids-loading in formulating solid propellants. It is preferred to change its crystal morphology into octagonal shapes and at the same time encapsulate it with a hydrophobic polymer. ADN was mixed with toluene, graphene, citryl ammonium butyl, Cab-o-sil, and a coating polymer (polystyrene or HTPB) and treated with ultrasound to obtain semi-spherical ADN-coated particles [160]. The method offers a reduction in operating temperature in that it eliminates ADN melting in the shape-altering and prilling process used by others. The ADN processed by this method had a similar particle size and thermal stability compared to ADN made by a conventional ADN melt-prilling method. The ultrasound-treated coated ADN particles showed significant reduction in moisture absorption, from 68 to 16% at 65% relative humidity.

ADN is difficult to use in solid propellants due to its high surface polarity and strong hygroscopicity. An improved grade of ADN was prepared by coating spherical ADN particles using ultrasonic and *in situ* coating technology [161]. The properties of coated ADN prills were characterized by SEM–energy-dispersive X-ray spectroscopy (EDS), XRD, DSC-TGA, IR spectroscopy, impact sensitivity, friction sensitivity, the dryer balance method, and the creation of propellant mixes. Results showed that the sphericity of the coated ADN prills was less than 1.5, and the crystal form remained unchanged. The peak temperature of thermal decomposition was increased by 11 °C, the onset temperature of thermal weight-loss temperature was delayed by 15 °C, and the impact sensitivity was increased by 3.6 J. Under a condition of 30 °C and relative humidity of 75%, the saturated hygroscopicity of coated ADN prills decreased from 55% to less than 2.5%. Under a condition of 59% relative humidity, the saturated hygroscopicity of coated ADN prills was further reduced to 1.2%. Compared with an earlier HTPB propellant containing raw ADN, the porosity of the propellant containing coated ADN prills was significantly reduced. See also [162, 163].

3 Physical Properties of Ammonium Dinitramide

ADN, ammonium dinitramide, azanium dinitroazanide, $\text{NH}_4\text{N}(\text{NO}_2)_2$, $\text{N}_4\text{H}_4\text{O}_4$, CAS RN [140456-78-6], $M = 124.0569$ g/mol. Although discovered only a few decades ago, the physical properties of ADN have been thoroughly measured. Although some of the oxygen in this molecule is tied up for burning the hydrogen from the ammonium ion to form water, ADN has a high oxygen balance, +25.79%.

3.1 Melting Point and Phase Diagrams of Ammonium Dinitramide

3.1.1 Melting Point of Ammonium Dinitramide

The melting point of ADN prills as determined by DSC is 365.04 K (91.89 °C), which is slightly lower than that of recrystallized ADN, which melts at 365.6 K (92.44 °C) [102]. Other reports indicate that the ammonium salt of dinitramidic acid melts at 365 K (92 °C) and starts to decompose at 403–408 K (130–135 °C). Table 4 gives a summary of reported melting-point data for ADN.

Table 4: Melting point of ammonium dinitramide.

Sample condition	Melting point		DSC heating rate	DSC heat of melting	References
	K	°C	°C/min	J/g	
Prilled	365.04	91.89			[102]
Recrystallized	365.59	92.44			[102]
SRI-12	361	88			[164]
Recrystallized	365.6	92.5			[2]
Crystals	365 ± 1	92 ± 1	5	138 ± 3	[165]

Crystals	365	92	5	—	[170]

^aPeak temperature of DSC endotherm

In addition to measuring the melting point of ADN, it has been attempted to predict the melting point of ADN and other nitramines based on theoretical molecular orbital calculations [171]. This can be applied to calculating the melting point of complex molecular and ionic solids and nanoparticles. Various approaches for simulating melting and computing the thermodynamic melting point were identified along with some force-field calculations that have been used in simulations of the melting of molecular and ionic solids, and the different structural, energetic, and dynamical quantities used to characterize the melting transition were described.

The surface tension of molten ADN determines the droplet size during prilling of ADN. Surface energy and crystallization phenomena of ADN were characterized during recrystallization from the melt [172]. The surface tension of molten ADN at 370 K (97 °C) was measured to be 89 mN/m. The wetting angles between molten ADN and different solid surfaces (polytetrafluoroethylene, glass, steel, and aluminum) were also determined. The wettability depends on the surface tension of molten ADN, the free surface energy of the solid surfaces, and the interfacial tension between the solid and liquid. Observations of the recrystallization behavior of molten ADN showed that nucleation does not occur readily, even at rapid cooling rates of 70 K/min. Crystallization can be initiated by insemination with seed crystals.

3.1.2 Phase Diagram of Ammonium Dinitramide

The pressure/temperature reaction-phase diagram for ADN was determined using a high-temperature-high-pressure diamond anvil cell with optical polarizing light microscopy, FTIR spectroscopy, laser Raman spectroscopy, and energy-dispersive XRD, and was also compared to RDX, HNIW, and *p*-nitroaniline [173, 174]. The starting material for all experiments was the α polymorph of ADN. Some results suggested a new monoclinic phase above 2.0 GPa. The phase diagram was determined between ambient pressure and 10.0 GPa over the entire temperature range from 198 K (−75 °C) to the decomposition temperature near 393 K (120 °C) (Figure 9). The diagram delineates the melting curve for α -ADN.

ADN exhibits a reversible phase transition in α -ADN forming a new high-pressure monoclinic polymorph, β -ADN. The monoclinic α phase is stable up to about 2.0 GPa between 198 and 393 K (−75 and +120 °C). The high-pressure β phase, which is also

Figure 9: High-pressure phase diagram for ADN. (Reprinted and modified from [174], with permission from © 1996 American Chemical Society; permission conveyed through RightsLink.)

monoclinic, is stable above 2.1 GPa between 198 and 393 K (−75 and +120 °C). The β phase cannot be retrieved to ambient conditions but reverts to the α phase as the pressure is lowered to below about 2.0 GPa. The $\alpha \leftrightarrow \beta$ transition is reversible and can be approached from both the α and β phases, but the spread in the data points is large. The $\alpha \leftrightarrow \beta$ transition pressure is estimated to be 2.0 ± 0.2 GPa. At high pressures and above 393 K (120 °C), a solid-phase rearrangement and decomposition occur to form AN and N_2O .

3.1.3 Binary Phase Diagrams of Ammonium Dinitramide Solutions

The phase diagram of the ADN/water system is very similar to that of the AN/water system. Figure 10 shows the binary phase diagram with melting point versus a mass fraction scale, and Figure 11 shows the same data with a mol fraction scale [175]. Note that changing the abscissa scale changes the shape of the curve from concave to convex. The eutectic is at 16.9 mol percent (58.3 mass-%) ADN with a melting point of 258 K (−15 °C). These data are very similar to those for AN.

Another phase diagram is shown in Figure 12 from reference [176]. From the phase diagram, the eutectic composition mass fraction was found to be $w_{\text{ADN}} = 0.58$, which corresponds to a mol fraction (x_{ADN}) equal to 0.167. For comparison, the eutectic composition reported by others for the AN/water system is $w_{\text{AN}} = 0.428$ and $x_{\text{AN}} = 0.144$, with a melting point in the range of 256.4 to 256.3 K (−16.7 to −16.8 °C).

3.2 Solubility of Ammonium Dinitramide in Solvents

ADN is quite soluble in a number of polar solvents and only sparingly soluble in non-polar solvents. The solubility of ADN in water at different temperatures is summarized in Table 5.

Table 5: Solubility of ADN in water at different temperatures.

Temperature		Solubility
K	°C	Mass-%
258	-15.0	58.3 ± 0.2
263	-10.0	62.7 ± 0.2
273	0.0	69.3 ± 0.1
298	20.0	78.1 ± 0.1

Data source: [176]

Measurements below 258 K (-15 °C) were prevented because of incipient freezing of the aqueous ADN solution. The measurement procedure was double-checked by measuring the solubility of AN in water at 293 K, and it was found to be 65.6 mass-%, which is

Figure 13: Solubility of ADN in 1-propanol. (Reprinted and modified from [90] with permission granted by ICT.)

in good agreement with data in the literature (65.5%). The solubility of ADN in water is considerably higher than that of AN.

Solid oxidizers like ADN are readily soluble in hydrogen peroxide, and such solutions have been evaluated as liquid oxidizers, which have a lower freezing point and higher density than plain hydrogen peroxide. Many of these solutions do not have sharp freezing points but instead have glass transition points as the sample temperature decreases. The ignition delays of ADN/HTP solutions with an ionic liquid fuel, 1-allyl-3-methylimidazolium dicyanamide, were measured [177].

Numerous non-aqueous solvents have been evaluated to facilitate the separation of freshly produced ADN from reactants and by-products [178]; 357 g ADN dissolves in 100 g water at room temperature to make a saturated solution.

A patent describes a monopropellant consisting of at least 65% ADN in ammonia with at most 5% water, freezing at 233 K (−40 °C) [179]. Physical properties of this solution are shown in *Encyclopedia of Monopropellants*.

The solubility of ADN in 1-propanol and 1-octanol was measured as part of a search for solvents from which ADN can be recrystallized to obtain crystals with more favorable length/diameter ratios [90]. From the natural cooling experiments, 1-propanol turned out to be the most promising solvent to obtain crystals with a low aspect ratio. The ADN recrystallized from three different alcohols was characterized by SEM imagery, XRD, DSC, and TGA. The solubility of ADN in 1-propanol is shown in Figure 13. Similar data are available for ADN in 1-octanol. The solubility of ADN in various solvents is summarized in Table 6.

Table 6: Solubility of ADN in organic and inorganic solvents.

ADN is soluble in *N*-methyl pyrrolidone, [180] and its heat of solution was measured. The obtained enthalpies can be regarded as the enthalpies at infinite dilution because of the very low molalities used in this experiment. The differential enthalpies ΔH_{sol} were -22.26 , -21.85 , -22.84 , and -23.11 kJ/mol for ADN in NMP at 298, 303, 308, and 313 K, respectively. The molality had little effect on the values of the molar enthalpy at each temperature.

3.3 Hygroscopicity of Ammonium Dinitramide

The hygroscopic properties of dinitramide salts vary widely. The ammonium salt of dinitramidic acid is very hygroscopic (more so than AN), while quaternary alkylammonium, aminoguanidinium, and acetamidinium salts are less hygroscopic.

Computations can explain the affinity between ADN and water leading to unwanted hygroscopicity, but they do not offer any methods to circumvent this problem in propellants.

DFT and a dispersion-corrected DFT have been used to investigate the hygroscopicity of ADN [181]. Calculation results showed that the gaseous ADN has a strong hydrogen bond. But the ionic pair structure

is stabilized upon the addition of water molecules. Natural bond orbital calculations suggest that the intra-molecular and inter-molecular orbital interactions make the system stabilized as a whole. An energy decomposition analysis revealed that the interactions between ADN and H_2O are dominated by electrostatic and orbital interactions. The formation reactions become more spontaneous with the increasing number of water molecules, but they can be weakened by increasing temperatures from 200 to 400 K. A more realistic cluster model of the interactions between ADN and H_2O was described using a molecular dynamics method.

The hygroscopicity of spherical ADN and its changes of morphology in the process were analyzed using a dynamic hygroscopic analytical method and SEM [182, 183]. The hygroscopic process can be divided into three stages: gentle moisture absorption, dramatically enhanced moisture absorption, and deliquescence. The first and second stages involve the interaction of water vapor and the surface of solid ADN, while the third stage is the interaction of water vapor and the ADN liquid membrane surface. The hygroscopic process of the first stage is a multi-molecular layer adsorption between water vapor and ADN, which adsorbs in accordance with the Brunner–Emmett–Teller theory model, and the force between water vapor and ADN plays a leading role in the hygroscopicities of ADN. The hygroscopic mechanism of the second stage can be explained by a capillary condensation theory. See also [184, 185].

The critical relative humidity for ADN is 55.2% at 25 °C [176]. This means that the relative humidity must be less than 55.2% to prevent ADN from absorbing moisture

from the atmosphere during processing. ADN is more hygroscopic than AN, and the hygroscopicity of crystalline ADN is more severe than that of AP. This property seriously affects its use when ADN is considered as a drop-in replacement for AP. This different hygroscopicity is possibly associated with their different crystal structures.

The hygroscopicity of ADN was studied at various controlled relative humidity levels [123]. It would be ideal to handle it only in a desert climate where it always stays very dry (0.02% H_2O). ADN samples were equilibrated in controlled humidity chambers with 38 and 58% relative humidity. In the 58% relative humidity chamber, their water content was 0.4% after 24 h and 1.76% after 95 h. In the 38% relative humidity chamber, the weight gain fluctuated between 0.06 and 0.08% for 94 to 1104 h. The moistened samples lost most of their water again after being stored at ambient desert conditions, and the water content dropped back down to 0.07% after 2 weeks. Similar tests were performed with two particle sizes of ADN at two different ambient relative humidity levels. The moisture absorption curves are shown in Figure 14 and 15. It is unusual that the equilibrium condition is achieved rapidly for the ADN samples at 62% relative humidity (160–180 h) but is slow at 74% relative humidity (320–370 h).

Comparing the hygroscopicity of crystalline ADN and AP, it is noted that the unwanted hygroscopicity of crystalline ADN is more severe than that of AP, and it seriously affects its use [186]. An equilibrium moisture content of ADN could not be achieved even after 1200 min when the relative humidity values were 65 or 80% (Figure 16).

The water content of ADN slightly decreased at 45% relative humidity because its critical relative humidity is 55.2%. The conditions at relative humidity 52% are completely similar to those at relative humidity 45%; therefore, the two lines overlap. At both 65 and 80% relative humidity, the water content in ADN was higher than

Figure 14: Moisture uptake of ADN at 62% relative humidity (Reprinted and modified from [58] with permission granted by Dr. Santhosh 8-Feb-2021.)

Figure 15: Moisture uptake of ADN at 74% relative humidity (Reprinted and modified from [58] with permission granted by Dr. Santhosh 8-Feb-2021.)

0.4 mass-% in less than 20 min. In 60 min at 65 and 80% relative humidity, the water content reached about 1.4 and 1.8%, respectively.

3.4 Phase Diagrams of Ammonium Dinitramide Mixtures

3.4.1 Ternary Phase Diagrams of Ammonium Dinitramide Solutions

Ternary systems containing ADN and water and a third ingredient could be ternary mixtures containing two oxidizers or systems containing one oxidizer, a fuel, and a solvent. The third ingredient could have a salting-out effect (as in the case of adding ethanol or methanol) or a salting-in effect (only a few additives improve the solubility of ADN).

The solubility of ADN in water, methanol, and water/methanol mixtures was measured and compared to that of AN and HNF. ADN is more soluble in either solvent than either of the other two oxidizers (Table 7).

Table 7: Solubility of different oxidizers in water/methanol mixtures at 293 K (20 °C).

Oxidizer	Water/methanol (mass-%)		
	100/0	50/50	0/100
ADN	78.1 (0.07)	71.4 (0.15)	46.5 (0.14)
AN	65.6 (0.33)	47.5 (0.42)	14.6 (0.06)
HNF	52.9	No data	18.2

Solubility in mass-% solute (g solute in 100 g solution);
standard deviations in parentheses

Data source: [187]

The data from Table 7 are illustrated in Figure 17.

Figure 17: Solubility of ADN in water/methanol mixtures at 293 K (20 °C) in comparison to that of AN and HNF. (Reproduced and modified from [187].)

Additional solubility data for ADN in methanol/water mixtures were obtained at 273 K (0 °C) (Table 8).

Table 8: Solubility of ADN in water/methanol mixtures at 273 K (0 °C).

Water/methanol (mass-%)			
100/0	70/30	60/40	50/50
69.3 (0.10)	63.5 (0.30)	60.6 (0.25)	57.0 (0.04)

Solubility in mass-% solute (g solute in 100 g solution);
standard deviations in parentheses

Data source: [187]

The ternary diagram of ADN/methanol/water mixtures was constructed from published data [187] and is shown in Figure 18. Additional data were entered for AN, hydroxylammonium nitrate (HAN), and HNF, which makes the diagram a bit confusing.

Figure 18: Ternary phase diagram of oxidizer solutions with methanol. (Reproduced and modified from Kappenstein, Batonneau, Perianu and Wingborg [175] with permission from Dr. Charles Kappenstein.)

There are four phase boundary lines emanating from the right side of the triangle and running toward the fuel corner (left corner). The compositions above those lines are liquid, and the compositions below the lines contain undissolved oxidizer. The line for ADN is shown in blue. In addition to the colored phase boundary lines, a red line dropping from the water corner (top corner) of the diagram marks the stoichiometric ratio of oxidizer : fuel (OMOX line). If one wants to select an optimum high-performance ternary propellant composition, one would want to select a composition close to the OMOX line and above the phase boundary.

A composition that meets these criteria would be 72% ADN, 13.4% methanol, and 14.6% water. The theoretical specific vacuum impulse of such a monopropellant would be 2698 N s kg^{-1} (275 s) ($p_c = 2 \text{ MPa}$, $A_e/A_t = 50$), compared to 2300 N s kg^{-1} (234 s) for hydrazine.

3.4.2 Binary Phase Diagrams of Ammonium Dinitramide Mixtures

Mixtures of ADN with other dinitramide salts or other ammonium salts can give solid solutions and oxidizers with improved sensitivity or performance properties.

ADN melts between 365 and 368 K (92 and 95 °C), depending on the amount of AN impurity present. The melting point can be as low as 328 K (55 °C) at the ADN/AN (70/30 mol percent) eutectic point. The melting of an ADN/AN mixture containing 5% AN starts at 328 K (55 °C), and temperature-resolved XRD shows transitions in the crystal structure [188]. AN expands the ADN lattice by forming a solid solution that favors the formation of a eutectic melt.

Mixtures of ADN with some hydrogen bond donor compounds result in the formation of ionic liquids that have been evaluated as monopropellants [189]. For instance, acetamide that melts at 355.5 K (82.4 °C) forms a eutectic with a melting point of 280 K (7 °C), for a melting point of ADN depression of $\Delta T = 86$ °C. Similarly, oxalic acid, which melts at 463 K (190 °C), forms a eutectic melting at 323 K (50 °C) for a depression of $\Delta T = 43$ °C. Urea, which melts at 406 K (133 °C), forms a eutectic melting at 325 K (52 °C) for a depression of $\Delta T = 41$ °C. It was found that the amount of melting point depression depends on the hydrogen bond donor's molecular volume.

Binary eutectic mixtures of ADN with methylammonium nitrate and ternary mixtures of ADN with urea and methylammonium nitrate are ionic liquids at room temperature and were evaluated as energetic ionic liquid propellants [190, 191]. The theoretical specific impulse of such mixtures is potentially higher than that of SHP163 or LMP103 (see *Encyclopedia of Monopropellants*, chapter “Ammonium Dinitramide-Based Monopropellants”). These ionic liquids were characterized by DTA, TGA–mass spectroscopy, and IR and mass spectrometric analysis of their thermal decomposition products. In the DTA, the first exotherm started at 423 K (150 °C).

The addition of ADN to AN is a means of eliminating the troublesome IV → II phase transition (see *Encyclopedia of Oxidizers*, chapter “Nitrate Oxidizers”).

A detailed study of the ADN/AN binary system was based on both experimental and computational methods. Binary ADN/AN phase diagram calculation were performed using a basic model based on ideal ionic liquid and pure non-miscible solid phases and were compared to the experimental phase diagram determined by DSC analyses of 24 prepared compositions [192]. The ADN/AN phase diagram illustrated in Figure 19 is based on the $T_{\max}$ peak temperatures of the DSC experiments and contains a combination of experimental and computed data. Results from computations and experiments are not in perfect agreement. The locations of the calculated and measured eutectic points are about 0.17 mol-fraction units apart. The measured eutectic has a melting point of 330 K (57 °C) and occurs at an ADN mol fraction of 0.6.

3.5 Density of Ammonium Dinitramide

The density of solid crystalline ADN is 1.81 g/cm^3 . That is higher than the density of AN and lower than the density of AP. HAN and HNF have higher densities than ADN. The density of molten ADN at 100°C is 1.560 g/cm^3 [193]. A summary of literature data on the density of ADN is given in Table 9. Additional XRD density data are in the crystallographic properties table (Table 14).

Table 9: Density of ammonium dinitramide.

Density g/cm ³	Temperature K	Method	References
1.801		X-ray	[164]
1.808		Volumetric	[193]
1.824 ± 0.009		Pycnometric	[137]
1.831		X-ray	[194]
1.831	223	X-ray	[195]
1.8184	293	X-ray	[169]
1.872	90	X-ray	[196]
1.807	295	Synchrotron	[90]

Based on pycnometric measurements, the density of spray-prilled ADN was 1.824 ± 0.009 g/cm³ (average of six measurements) [137].

The coefficient of thermal expansion of ADN was measured using temperature-resolved XRD [188]. Density versus temperature data from different sources have been plotted in Figure 20 and give a linear relationship.

Figure 20: Density of ADN. (Reprinted and modified from [90] with permission granted by ICT 12-Mar-2021.)

By extrapolating the liquid density in Figure 21 (in Section 3.5.1.1) to higher temperature, the liquid density of ADN at 373 K (100 °C) was estimated to be 1.61 g/cm³. This is 11% lower than the density of solid ADN at ambient conditions. Thus, pure molten ADN at 373 K (100 °C) will, on crystallization and cooling to ambient temperature, shrink by 11% [176].

3.5.1.1 Density of Ammonium Dinitramide Solutions

If the density of ADN solutions is plotted against the mass fraction, the curve is slightly concave. Figure 21 shows the density of aqueous ADN solutions at 298 K in comparison to densities of two other oxidizers [175]. The AN data were measured at a temperature higher than room temperature (323 K) because AN is less soluble in water than the other two oxidizers.

Figure 21: Density of aqueous ADN solutions in comparison to other oxidizers. (Reproduced and modified from Kappenstein, Batonneau, Perianu and Wingborg [175] with permission from Dr. Charles Kappenstein.)

The molar volumina of ADN and other oxidizers was measured so that the theoretical density of oxidizer/fuel/water mixtures in monopropellants could be calculated assuming additive behavior of the molar volumina in mixtures. As a start, the reciprocal density (i.e., the specific volume) was plotted versus the mol fraction of oxidizer as shown in Figure 22.

The curves in Figure 22 are straight lines, such that their shape can be expressed by a simple linear function

$$V_m = V_{m\text{H}_2\text{O}} \times X_{\text{H}_2\text{O}} + V_{m\text{ADN}} \times X_{\text{ADN}}$$

$$V_m = V_{m\text{H}_2\text{O}} + (V_{m\text{ADN}} - V_{m\text{H}_2\text{O}}) \times X_{\text{ADN}}$$

Figure 22: Molar volume of ADN solutions versus mol fraction of ADN in comparison to other oxidizers. (Reproduced and modified from Kappenstein, Batonneau, Perianu and Wingborg [175] with permission from Dr. Charles Kappenstein.)

The molar volumina of the salts are derived from the intercept of the lines. The results are summarized in Table 10.

Table 10: Extrapolated molar volume and density of pure ionic liquid oxidizers.

Compound name	Formula	Molar volume, mL/mol	Density of pure ionic liquid (no solvent), g/cm ³
Ammonium nitrate	NH ₄ NO ₃	52.00 (15)*	1.539 (5)*
Ammonium dinitramide	NH ₄ N(NO ₂) ₂	74.06 (13)	1.675 (3)
Hydroxylammonium nitrate	NH ₃ OH NO ₃	55.45 (19)	1.732 (6)

*Numbers in parentheses designate the standard deviation of the last digits.

Data source: [175]

A similar set of density and molar volume measurements was reported 2 years later (Wingborg [176]). The density of ADN solutions in comparison to the density of AN solutions in water at 298 K is shown in Figure 23.

Figure 23: Density of ADN and AN solutions in water at 298 K. (Reprinted and modified from [176], with permission from © 2006 American Chemical Society; permission conveyed through RightsLink.)

The molar volumes of ADN and AN in aqueous solutions obtained from a linear regression analysis are tabulated in Table 11.

Table 11: Molar volumes of ADN and AN in aqueous solutions at 298 K (25°C).

	ADN	AN
Linear correlation coefficient r^2	0.99995	0.99975
Molar volumes for water, V_w , cm^3/mol	17.98 ± 0.03	17.98 ± 0.04
Molar volumes for salts, V_s , cm^3/mol	74.08 ± 0.17	51.23 ± 0.24
Density of the salts in the liquid state, ρ_s , g/cm^3	1.675 ± 0.004	1.562 ± 0.007

Data source: [176]

3.6 Vapor Pressure and Sublimation of Ammonium Dinitramide

Sublimation of undecomposed ADN is a prime step in the decomposition and burning of ADN. The mechanism for sublimation of ADN has been investigated quantum mechanically with generalized gradient approximation plane-wave DFT calculations [197]. The calculated total sublimation enthalpy for $\text{ADN}(\text{S}) \rightarrow \text{NH}_3(\text{G}) + \text{HN}(\text{NO}_2)_2(\text{G})$, 188 kJ/mol (44.9 kcal/mol), was in good agreement with the value of 176 kJ/mol (42.1 kcal/mol) predicted for the one-step sublimation process and the value of 184 kJ/mol (44.0 kcal/mol) using experimental thermochemical data.

3.7 Viscosity and Surface Tension of Ammonium Dinitramide Solutions

The surface tension of propellants is important for the design of injection orifices and passive propellant management devices in propellant tanks operating in zero gravity.

The surface tension and the wetting angles of molten ADN were measured in order to select proper equipment (nozzles, agitator paddles) and materials of construction in contact with ADN [119]. The surface tension of molten ADN at 370 K (97°C) is relatively high due to the molecular structure of ADN and the ion–ion interactions in the melt. The surface tension of molten ADN is 89 mN m^{-1} , and the surface tension of an 80 mass-% solution of HAN in water is 88 mN m^{-1} [198].

3.8 Thermal Conductivity and Thermal Diffusivity of Ammonium Dinitramide

The heat capacity, thermal conductivity, and thermal diffusivity of a range of other oxidizers, binders, and rocket propellants were determined and compared with data in the literature [199]. The thermal diffusivity α of ADN for the range from 20 to 65°C can be described by the linear equation

$$\alpha = 1.89 \times 10^{-3} - 1.74 \times 10^{-6}t$$

where α is the thermal diffusivity in cm^2/s and t is the temperature in °C. Likewise, the thermal conductivity λ of ADN for the range from 293 to 338 K (20 to 65°C) can be described by the linear equation

$$\lambda = 1.08 \times 10^{-3} - 5.78 \times 10^{-7}t$$

where λ is the thermal conductivity in $\text{cal cm}^{-1} \text{s}^{-1} \text{°C}^{-1}$ and t is the temperature in °C. Similar data are contained in the same publication for a wide range of oxidizers, binders, and solid propellants.

3.9 Thermophysical Properties of Ammonium Dinitramide

3.9.1 Heat Capacity of Ammonium Dinitramide

The heat capacity (C_p , solid) of ADN is $1.8 \pm 0.2 \text{ J g}^{-1} \text{°C}^{-1}$ [193]. The heat capacity of ADN in the range 293–338 K (20–65°C) can be described by the following linear equation [199]:

$$c_p = 0.308 + 3.61 \times 10^{-4}t$$

where c_p is the heat capacity in $\text{cal g}^{-1} \text{°C}^{-1}$ and t is the temperature in °C.

3.9.2 Heat of Fusion of Ammonium Dinitramide

The heat of fusion of ADN was estimated to be $17.4 \text{ kJ/mol} = 140.14 \text{ J/g}$. The entropy of fusion was estimated to be $47.8 \text{ J K}^{-1} \text{ mol}^{-1}$ [198].

Experimental heat of fusion measured during melt-casting of large charges of ADN was $130 \pm 5 \text{ J/g}$ [193]. Other sources give the heat of fusion as 140 J/g [200] or 142 J/g [14]. Based on DSC measurements, several other samples had a heat of fusion of $146.0 \pm 0.21 \text{ J/g}$ (unprilled ADN) and $92.4 \pm 0.2 \text{ J/g}$ (prilled) [137]. Table 12 gives the heat of fusion of ADN in comparison to those of AN and AP.

Table 12: Heat of fusion and melting points of AN, ADN, and AP.

	ΔH_{fus}		T_{fus}	
	kJ/mol	kcal/mol	K	°C
AN	6.11	1.46	442.7	169.6
ADN	17.62	4.21	366.0	92.9
AP	29.30	7.00	513.1	240

Data source: [192]

3.9.3 Heat of Solution of Ammonium Dinitramide

When ADN is dissolved in water, the temperature of the mixture decreases substantially. This means that the heat of solution is positive and that the enthalpy of the solution increases by absorbing heat from the environment.

Enthalpies of formation and solution of ADN along with other salts of nitric and dinitramidic acids with organic amines were determined by combustion and solution calorimetry methods [201]. The enthalpy of solution of ADN in water at high dilutions was measured as $36.44 \pm 0.04 \text{ kJ/mol}$ ($8.71 \pm 0.01 \text{ kcal/mol}$).

The ADN heat of solution was measured using a solution/mixing calorimeter based on a dewar vessel equipped with a magnetic stirrer and a precision thermometer [202, 203]. The amount of water in the vessel was 100 g, and the sample weight was 1 g. The ADN heat of solution was found to be $+35.7 \text{ kJ/mol}$. For more concentrated solutions like those in monopropellants, the ADN heat of solution is only $+24 \text{ kJ/mol}$.

3.9.4 Enthalpy of Formation of Ammonium Dinitramide

Enthalpy of formation data for ADN reported in the literature vary considerably, most likely because of the poor quality of ADN (contamination by AN) used by some of the early investigators. Table 13 gives a historical summary of the numbers reported by different sources.

The enthalpy of formation of ADN was determined from experimental data of the enthalpy of dissolution of this salt [206]. The enthalpy of formation of the dinitramide

Table 13: Enthalpy of formation data for ADN.

$M = 124.0569 \text{ g/mol}; 8.0608 \text{ mol/kg}$

anion was calculated from four groups of independent data on burning and dissolution of nitraminic acid salts and salts with identical cations. Using combustion and dissolution calorimetry, the enthalpies of formation and dissolution of the salts of hydrazinium, guanidinium, aminoguanidinium, and triaminoguanidinium of nitric and dinitraminic acids were obtained and compared to literature data. Based on using the known enthalpy of formation of the nitrate ion, the enthalpies of formation of the cations in the infinitely diluted aqueous solutions were then calculated. The enthalpy of dissolution of ADN is $36.4 \pm 0.04 \text{ kJ/mol}$ ($8.71 \pm 0.01 \text{ kcal/mol}$). Using combustion calorimetry, the energy of combustion of ADN for a sample with purity greater than 99.9% was measured, and the best value for its enthalpy of formation was then $134.5 \pm 0.5 \text{ kJ/mol}$ ($32.16 \pm 0.11 \text{ kcal/mol}$).

Enthalpies of formation of cations (ammonium, hydrazinium, and a series of guanidinium ions) by themselves in infinitely diluted aqueous solutions were calculated using the known enthalpy of formation of the nitrate ion ($-206.8 \text{ kJ/mol} = -49.44 \text{ kcal/mol}$) [201]. The enthalpy of formation of the dinitramidic acid anion could then be determined based on the enthalpy of formation and solution of the acid salts. The enthalpy of formation of the dinitramidic acid anion averaged to $35.1 \pm 0.5 \text{ kJ/mol}$ ($8.40 \pm 0.13 \text{ kcal/mol}$). From these data, the enthalpy of formation of ADN was calculated as $-134.5 \pm 0.6 \text{ kJ/mol}$ ($-32.14 \pm 0.14 \text{ kcal/mol}$). This compares well with the enthalpy of formation of ADN that was measured for a sample with purity greater than 99.9% and turned out to be $-134.7 \pm 0.8 \text{ kJ/mol}$ ($-32.20 \pm 0.19 \text{ kcal/mol}$) based on the energy of combustion of ADN in a constant-volume calorimetric bomb. Combining calculated and measured enthalpies of formation of ADN leads

to a recommended weighted value of $-134.6 \pm 0.46 \text{ kJ/mol}$ ($-32.16 \pm 0.11 \text{ kcal/mol}$) for the enthalpy of formation of ADN. As of 2014, this seems to be the most reliable number found in the literature so far. This number is consistent with the enthalpies of formation of sodium, potassium, and cesium salts of dinitramidic acid that were determined as part of the same study.

A linear relationship seems to exist between the enthalpies of formation of nitrates and dinitramide salts having the same cation, as illustrated in Figure 24. Thus, if the enthalpy of formation for a nitrate salt (XN) is known, the enthalpy of formation of its corresponding dinitramide salt (XDN) can be estimated according to the equation

$$\Delta H_f(\text{XDN}) = \Delta H_f(\text{XN}) + 230n \left(\frac{\text{kJ}}{\text{mol}} \right)$$

where n is the number of anions per cation. Using the established data for the enthalpy of formation for AN (-365.6 kJ/mol), the enthalpy of formation for ADN was estimated to be -135.6 kJ/mol , which is in good agreement with the experimental value (-134.6 kJ/mol). The dissociation energy for ADN to dissociate into its ions is $255 \pm 12.5 \text{ kJ/mol}$, reference [105].

Figure 24: Enthalpy of formation of XDN/XN pairs divided by the number of anions per cation. Salts in parentheses were excluded in the linear regression analysis. (Reproduced and modified from [13].)

3.10 Molecular Properties of Ammonium Dinitramide

The high stability of the dinitramide anion is attributed to the resonance delocalization of the net negative charge over the molecular system, which strengthens those N—NO₂ bonds that are most susceptible to rupture. Three of the resonance forms are shown in Figure 25, which illustrates the conjugation between the nitro groups and the central nitrogen.

Figure 25: Three resonance structures of the dinitramide anion. (Reproduced and modified from [164].)

Actually, there are eight possible resonance forms of the dinitramide ion (Figure 26).

Figure 26: Eight resonance structures of the dinitramide anion. (Reproduced and modified from [208].)

Resonance forms 1 through 3 would most likely make major contributions to the statistical distribution. Forms 6 through 8 are less likely because they contain negative charges on two adjacent oxygen atoms, which would render the molecule less stable [208].

There are two possible locations of the hydrogen in dinitramidic acid: one on the central nitrogen (1), or on one of the oxygens (2). While there is only one stable nitro form, there are several stable conformers of the aci form (2).

Theoretical ab initio calculations for the free anion indicated that structure (1) with an equal negative charge distribution between the nitro groups is the more stable form, lying 9.4 kcal/mol lower in energy than structure (2) [209]. They determined the gas-phase acidities of isomers (1) and (2) as 1305 ± 8 and 1266 ± 8 kJ/mol (312.0 ± 2 and 302.6 ± 2 kcal/mol), respectively. For the free acid $\text{HN}(\text{NO}_2)_2$, Michels and Montgomery reported ΔH_0^f (0 K), a range from 119 to 124 kJ/mol (28.4–29.7 kcal/mol). In aqueous solutions, however, the initial anion structure distorts as a result of the low-energy barrier to rotation around the N–N bond.

The bond angles and bond distances in the dinitramide ion are shown in Figure 27.

Figure 27: Bond angles and bond distances in dinitramide ion.

The dinitramide ion is very flexible, with twisting around each of the N—N axes, and it can assume different shapes depending on the environment it is in. It will have different shapes in solution or in a solid state. And even in the solid state, its shape depends on the cations it is paired with.

Vibrational and electronic spectra of dinitramide and its salts $M^+N(NO_2)_2$ ($M = K, Na, Li, NH_4, Hg, Fe$), were studied under different conditions (aggregate states, solvents, and temperature) [210, 211]. The spectra were interpreted from experimental and theoretical data using the normal coordinate analysis method, leading to conclusions about the structure of the $HN(NO_2)_2$ molecule and its ion. It is surprising that the UV spectra of dinitramidic acid can differ dramatically depending on the preparation of the chemical, the solvent it is in, and the acidity of the solution (Figure 28).

IR and UV spectroscopic studies of the free dinitraminic acid showed that in the covalent state it can exist in two different forms. In one of these forms, (1), the proton is bound to the central nitrogen atom, $\text{HN}(\text{NO}_2)_2$. In the other form, (3), the proton is equally bound to two oxygen atoms of both nitro groups ([212]; Figure 29).

3.10.1 Molecular Structure of Ammonium Dinitramide

ADN is known to exist in two polymorphic forms: α -ADN and β -ADN. For $p < 2.02 \text{ GPa}$ ($2 \times 10^4 \text{ atm}$), α -ADN with a stable monoclinic prism crystal structure is observed, and β -ADN exists only at higher pressures ($p > 2.02 \text{ GPa} = 2 \times 10^4 \text{ atm}$) [174, 213].

3.10.1.1 Crystal Structure of Ammonium Dinitramide from X-Ray Diffraction

ADN forms monoclinic crystals with the space group designation $P2_1/c$. It possesses a twofold screw axis parallel to the b -axis, with a c -glide plane perpendicular to the screw axis [196]. The lattice parameters are $a = 6.908 \text{ \AA}$, $b = 11.895 \text{ \AA}$, $c = 5.638 \text{ \AA}$, and $\beta = 100.278^\circ$. One dinitramide anion and one ammonium cation comprise the asymmetric subunit cell, a unique subset of atoms from which all the other components of the unit cell can be assembled. The bonds between N1 at the apex and the nitrogens N2 and N3 of the two terminal nitro groups form an 113.8° angle. The two nitro groups are rotated

out of the N2—N1—N3 plane, one by 27.9°, the other by 22.8°. This rotation may be due to repulsive forces between the negatively charged oxygen atoms. This observation is also confirmed by measurement of the IR and Raman spectra of dinitramide salts. The calculated energy differences between twisted structures and those with either coplanar or perpendicular —NO₂ groups are very small, and the rotational barriers are less than 12.5 kJ/mol (3 kcal/mol). As a result of these small energy differences, the torsional angles observed in the crystal structures of different N(NO₂)₂[−] salts can vary by as much as 30° because of crystal packing effects and interactions with counterions. Table 14 gives a comparison of crystallographic data for ADN reported by different authors.

Table 14: Comparison of crystallographic data for ADN.

The charge distribution may have some effect on the extent of hydrogen bonding seen in ADN that helps to stabilize the molecule. Each of the four hydrogens of the ammonium cation participates in hydrogen bonding, but only three of the oxygen atoms participate in this scheme. A fairly thorough review of the crystal structure of ADN is given in reference [97] as part of an effort to modify the crystal habit of ADN crystals.

The XRD of several dinitramide salts with organic, inorganic, and metal cations revealed that these dinitramide salts exist in different conformations depending on the cation present [195]. In addition to ADN, the crystal structures of the lithium, potassium, and cesium salts of dinitramidic acid were analyzed using XRD. The theoretical and structural studies of the dinitramide anion showed that it is quite flexible and adopts different conformations depending on its environment. Ideal minimum energy conformation would be a C₂ symmetry. However, dinitramide salts show a diversity of conformations with C₁, C_s, and predicted C₂ symmetry. No two dinitramide salts give isostructural conformers. The conformation adopted by the dinitramide anion is quite different, with different bent, twist, and torsional angles. The experimental results have been interpreted by and compared to extensive molecular orbital and electron density theoretical calculations.

XRD is the preferred tool for the investigation of the crystal structures of all energetic materials. Crystallite size and microstrain of ADN prills can be investigated by means of XRD [215, 216]. The investigations correlate the size/strain broadening with particle processing history and mechanical sensitivities. Compressibility can be different in different axes of the crystal. Shock loading may result in rapid compression in one axis but not in the other, leading to hot spots and accidental ignition of energetic materials. Anisotropic diffraction peak broadening was found for some of the energetic materials. Whereas 2 θ positions and intensities of XRD peaks yield information on crystal structures, peak profiles (e.g., width at half-height) are related to the real structure determined by crystallite sizes, shapes, and microstrains. Microstrains are left behind after grinding of the materials or as the result of imperfect (hastened) crystal growth. The size/strain broadening of ADN XRD peaks was measured and interpreted based on crystal geometry, contaminants, and internal crystal defects, and also in comparison to similar measurements on RDX and FOX-7 [217–219]. ADN microstrain broadening was moderate compared to FOX-7 or RDX; all values were below $0.02 \text{ \AA}^{-1}$ (reciprocal peak width).

Comparing the hygroscopicity of crystalline ADN and AP, it is noted that the unwanted hygroscopicity of crystalline ADN is more severe than that of AP, and it seriously affects its use. This quite different behavior is associated with their different crystal structures. XRD single-crystal diffraction data showed that vast hydrogen bond networks link the ADN structure [186]. The 3D structure of ADN joined by hydrogen bonds is an unusual twofold 3D interpropagation network structure, and the hydrogen bonds in the ADN crystal are much shorter than those in AP because of the special structure. The hydrogen bonds between ADN and H₂O were assayed by IR spectroscopy. DSC thermograms of moist ADN and AP crystals also confirm that, because of the stronger hydrogen bond between ADN and H₂O molecules, large amounts of bound H₂O are present in ADN crystals besides some unbound H₂O. All hydrogen atoms of the NH₄⁺ ions are involved in hydrogen bonds in the ADN crystal. All but one of the oxygen atoms participate in hydrogen bonding.

The melt crystallization behavior of ADN during cooloff in the course of prilling operations was observed by XRD and depends on ADN quality, humidity, maximum temperature of temperature cycles, and the type of liquid phase suspension agents [220]. Freshly prepared ADN prills undergo slow structural changes during storage following their preparation, in particular if they are not stored under absolutely dry conditions. Such changes can be followed by XRD [221].

3.10.1.2 Crystal Structure of Ammonium Dinitramide from Neutron Diffraction

Neutron diffraction measurements complement the information already obtained with XRD and confirm or sometimes contradict the XRD results. Neutron powder diffraction patterns of ADN were collected at pressures up to 4.03 GPa [222, 223]. All of the patterns could be indexed and fitted to a monoclinic unit cell based on that found at ambient pressure. Above 2.99 GPa, significant broadening of the diffraction peaks

Figure 30: Variation of lattice parameters of ADN as a function of pressure. (Reproduced and modified from [222] with permission granted by Dr. Colin Pulham 15-Feb-2021)

was observed, indicative of the non-hydrostatic behavior of HT-70 (a perfluorinated polyether in which the crystals are suspended), and this prevented the collection of useful data above 4.03 GPa. Figure 30 shows the variation of ADN lattice parameters with pressure and highlights the higher compressibility along the *b* axis consistent with the weaker intermolecular interactions in that direction.

No sign of the first-order phase transition reported by Russell et al. was observed up to 4.03 GPa under these conditions. To test whether this apparent difference in behavior originated from the use of the perdeuterated compound, a separate experiment using $\text{NH}_4\text{N}(\text{NO}_2)_2$ was performed using angle dispersive powder XRD up to 5.5 GPa; this, too, showed no sign of a phase transition. At 2.5 GPa, several of the longer H-bonding interactions had substantially shortened, e.g., $\text{D4}\cdots\text{O2B}$ distance had decreased from 2.43 Å to 2.24 Å, and $\text{D2}\cdots\text{O3A}$ distance had decreased from 2.13 Å to 1.94 Å.

3.10.1.3 Molecular Structure of Ammonium Dinitramide from Computations

The molecular structure of energetic compounds is closely related to their thermal stability and energy content. Strong bonds and high symmetry result in a thermally stable molecule. What separates a potentially useful molecule from one that is not is the rate at which decomposition occurs, or the kinetic stability, which is

more difficult to predict than the heat of formation. Quantum chemical studies are a useful tool in predicting decomposition rates and should precede synthetic efforts. Ideally, a high-energy-density material (HEDM) suitable for safe handling at room temperature should have a free-energy activation barrier for decomposition that exceeds 125.5 kJ/mol (30 kcal/mol). This value is estimated assuming first-order decomposition kinetics and corresponds to a half-life of 35 years at room temperature.

Even prior to the publication of the (re)discovery of dinitramides outside the USSR, a series of *ab initio* self-consistent field (SCF) calculations of the structures of the dinitramide anion, $\text{N}(\text{NO}_2)_2^-$, and some related molecules, $\text{HN}(\text{NO}_2)_2$ and $\text{N}(\text{NO}_2)_3$, showed that several factors affect their stabilities [208]. The proton affinity of $\text{N}(\text{NO}_2)_2^-$ was predicted as a measure of the acidity of $\text{HN}(\text{NO}_2)_2$. The interaction energy of $\text{N}(\text{NO}_2)_2^-$ with NO_2^+ to yield $\text{N}(\text{NO}_2)_3$, an unknown nitrogen oxide, can be calculated, but this compound has not yet been found. It would be a good oxidizer. The proton affinity of $\text{N}(\text{NO}_2)_2^-$ was found to be considerably greater than that of NO_2^- . The computed interatomic distances and bond angles of the dinitramide anion are shown in Figure 31.

Figure 31: Bond lengths and bond angles of dinitramide predicted by computational chemistry. (Reproduced and modified from [224].)

Atom–atom distances, bond lengths, and bond angles of the dinitramide ion predicted by computational chemistry are in close agreement with XRD data [224]. With improved computing capabilities of desktop computers, existing programs for calculating the electron charge density and electrostatic potential between ions have been modified to produce output suitable for improved visualization, in particular using color and 3D computer graphics. As an example, the charge density and electrostatic potential of three dinitramide salts were calculated and published [225, 226]. The aim of this work was to obtain information about the redistribution of electrons in the dinitramide anion, $\text{N}(\text{NO}_2)_2^-$ due to effects such as chemical bonding, based on XRD measurements. Three dinitramide salts (ammonium, monoprotonated, and diprotonated biguanidinium) were selected for charge density analyses on the basis of the observed variations of the dinitramide anion in the room-temperature structures and the potential future applications of these compounds as rocket propellants.

There were two objectives for this project. The first was to see whether the difference in the geometries of the $\text{N}(\text{NO}_2)_2^-$ ion is reflected in the size and shape of the bonding electron density using experimental methods. The second objective was to obtain the electrostatic potential of the materials based on the experimentally determined electron density distribution in order to gain some insight into the reactivity of the dinitramide ion. The different geometries produced observable differences in the deformation density. The electrostatic potential derived from the experimental electron density also showed variations with respect to the geometry and environment. These potentials have different minima and are also different from potentials produced from gas-phase semi-empirical and *ab initio* calculations.

In continuation of this study, the same group of authors found that the flexibility of the dinitramide ion is the result of mutually opposed effects of resonance stabilization and steric repulsion [227]. Evidence for this claim was found in the structural trends discovered in the analysis of X-ray data and additional energy calculations. The X-ray data also showed structural distortions brought about by different crystal environments. The calculations gave the energy required to distort a single molecular anion from the minimum energy structure to that found in the crystal. From these results, it was found that the crystal environment causes geometric variations of the ion that are site specific. On the other hand, energetically opposed effects of resonance and steric repulsion were responsible for the typically non-planar geometry of the ion and a complete separation between the NNO angles involving “inner” and “outer” oxygens.

Sorescu and Thompson have studied the structural properties of ADN crystal at ambient pressure by using DFT with pseudopotentials [228]. The optimization of the crystal structure was done with full relaxation of atomic positions and lattice parameters under $P2_1/c$ symmetry. The calculations were performed using periodic boundary conditions in all three directions. The predicted crystal structure was in good agreement with X-ray data and indicated no internal symmetry for the dinitramide ion, in contradistinction to the gas-phase theoretical results. The two halves of the dinitramine ion are twisted with respect to each other, while the NO_2 groups are rotated out of the N—N—N plane. The thermal expansion coefficients calculated for the model indicated anisotropic behavior. Subsequently, the authors used the same method to investigate the structural properties of crystalline ADN under hydrostatic compression in the pressure range of 0–300 GPa [229]. It was found that the ADN crystal maintains its monoclinic structure with $P2_1/c$ symmetry for pressures up to 10 GPa. Above 20 GPa, there is a transition to a P triclinic symmetry. The crystalline phase transition involves reorientation of the ammonium ions relative to the dinitramide ions as well as additional rotations of the NO_2 groups relative to the N—N—N plane of dinitramide ions. The lattice compression induces electronic changes that are similar to those observed for AN. An excellent and very detailed summary of the achievements of computational chemistry in predicting the properties of energetic materials, including ADN, AN, AP, and HAN, was given in a book chapter [230].

The structural model is capable of accurately predicting the temperature of the solid-to-liquid transition in ADN and estimating temperature dependence of the diffusion and viscosity coefficient in the liquid temperature range [231]. The melting point of crystalline ADN could be predicted by calculating the temperature dependence of the density, enthalpy, and radial distribution functions. However, the melting temperature of the perfect crystal calculated from the change in density was predicted to be in the range of 474–476 K, compared to the experimentally determined range of 365–368 K. The difference is attributed to superheating of the perfect crystal. The superheating effect can be eliminated by introducing assumed voids in the crystal structure. Calculations of the temperature dependence of the density of a supercell with eight or more voids predicted a melting temperature in the range of 366–368 K, which is in excellent agreement with the experimental value. The computed dependence of the melting temperature on pressure is also in excellent agreement with experiments. Similar calculations were performed for AN [232].

The electronic structure, vibrational properties, absorption spectra, and thermodynamic properties of crystalline ADN and AP were compared using DFT in the local density approximation [214]. The results showed that the p states for the two solids play a very important role in their chemical reactions. From the low-frequency to the high-frequency region, ADN has more degrees of freedom of motion modes for the vibrational frequencies than AP. The thermodynamic properties showed that ADN is easier to decompose than AP as the temperature increases.

DFT and the *ab initio*-based CBS-QB3 method were used to study possible decomposition pathways of dinitraminic acid, $\text{HN}(\text{NO}_2)_2$ (HDN), a potential ADN decomposition product, in gas phase [233]. The proton transfer isomer of HDN, $\text{O}_2\text{NNN}(\text{O})\text{OH}$, and its conformers can be formed and converted into each other through intra-molecular and inter-molecular proton transfer. The latter has been shown to proceed substantially faster via double proton transfer. The main mechanism for HDN decomposition was found to be initiated by a dissociation reaction, the splitting of nitrogen dioxide from either HDN or the HDN isomer. This reaction has an activation enthalpy of 152.7 kJ/mol (36.5 kcal/mol) at the CBS-QB3 level, which is in good agreement with experimental estimates of the decomposition barrier. The decomposition barrier of polarized dinitramide anions on the surface of solid ADN is reduced by 67 kJ/mol (16 kcal/mol), which may explain the anomalous solid state decomposition of ADN [234]. The anomalous solid-state decomposition of KDN and ADN can be explained from quantum-chemical calculations on large clusters of the two salts [235]. The decomposition mechanisms of dinitramide alkali metal and ammonium salts are highly topochemical in nature. Unsymmetrical cation coordination at the surface causes dinitramide anions to polarize and lose their resonance stabilization, reducing the decomposition barrier by >67 kJ/mol (>16 kcal/mol), compared to an isolated dinitramide anion in gas phase, to 125.5 kJ/mol (30 kcal/mol). This corresponds to a rate increase by more than 11 orders of magnitude. Both ADN and KDN decomposition is initiated by homolytic rupture of a weakened

nitrogen–nitrogen bond and dissociation into NO_2 radicals and NNO_2 radical anions, followed by production of N_2O and the corresponding nitrate. The stabilizing effect of water can be explained by its ability to reduce the polarization by hydrogen bond donation. In a similar manner, surface-active species are likely to act as stabilizers for metal and ADN salts. Spectroscopy studies of ADN and KDN crystals suggest that their surfaces are entirely covered by the decomposition products, AN and KNO_3 , respectively. Decomposition is governed by surface chemical processes involving polarized (twisted) dinitramide anions of reduced stability [236]. Donation of hydrogen bonds, antioxidant character, and basicity are properties believed to correlate with a compound's ability to act as a stabilizer for dinitramide salts.

The molecular surface structure of ADN and KDN crystals was represented by vibrational sum frequency spectroscopy and quantum chemical modeling [237]. Identification of key vibrational modes was made possible by performing DFT calculations of molecular clusters. The surface of KDN was found to be partly covered by a thin layer of the decomposition product KNO_3 , which, due to its low thickness, was not detectable by IR or Raman spectroscopy. In contrast, ADN exhibited an extremely inhomogeneous surface on which polarized dinitramide anions were present, possibly together with a thin layer of NH_4NO_3 . The experimental verification of polarized and destabilized dinitramide anions points the way to surface-active polymer support, stabilizers, and/or coating agents in order to extend the useful temperature range of ADN.

In addition to the dinitramide anion, there are other energetic nitrogen-based anions that can be envisioned to make good propellants, but some so far exist only on paper (or on the computer screen). The kinetic stability of dinitramide, trinitrogen dioxide, pentazole, and oxopentazole anions was evaluated in the gas phase and in solution by using high-level *ab initio* and DFT calculations [207, 238]. Theoretical UV spectra, solid-state heats of formation, density, and propellant performance for the corresponding ammonium salts were predicted. All calculated properties for dinitramide were in excellent agreement with whatever little experimental data were available for comparison. The standard enthalpy of formation of solid ADN was predicted to be -151 kJ/mol (-36.2 kcal/mol) based on quantum mechanical calculations [207], but this is quite different from the recommended experimental value of 134.6 kJ/mol .

Comparison of the IR and Raman spectra of isotopically substituted dinitramide salts in the solid state and in solution has provided new information on the structure and topology of the electron charge density in the dinitramide $\text{N}(\text{NO}_2)_2^-$ anion [211]. The frequency assignments were made with the help of quantum-mechanical force-field calculations and normal-coordinate analysis. The harmonic vibrational spectrum of the dinitramide anion calculated at the B3LYP/6-31+G(d) level in the presence of solvent correlated best with the experimental data.

Researchers have attempted to predict the melting point of ADN and other nitramines based on theoretical molecular orbital calculations [171]. This method can be applied to calculating the melting point of complex molecular and ionic solids

and nanoparticles. Various approaches for simulating melting and computing the thermodynamic properties were described along with force-field calculations that have been used in simulations of the melting of molecular and ionic crystalline solids, and the different structural, energetic, and dynamical quantities used to characterize and predict the melting transition were described. See also [90, 178, 239, 240].

3.10.2 Optical Properties of Ammonium Dinitramide

3.10.2.1 UV-Visible Absorption Spectra of Ammonium Dinitramide

All dinitramide salts are photosensitive and may decompose while a UV spectrum is recorded. A solution of ADN in water shows UV absorption maxima at 212 and 284 nm (Figure 32). The peak at 284 nm is characteristic for the dinitramide ion. The intensity of the peak is concentration dependent. Dinitramides are not stable in acidic environment and thus the concentration will decline at low pH.

Figure 32: UV spectrum of ammonium dinitramide. (Reprinted and modified from [58] with permission granted by Dr. Santhosh 8-Feb-2021.)

The knowledge of the molar extinction coefficient ϵ of ADN is important for on-line process monitoring of the formation of ADN, for determining the yield, and also for verifying the purity of the ADN product. The molar extinction coefficient of ADN in different solvents such as water, acetonitrile, and methanol was determined [58]. The extinction coefficient at 284 nm in water is $5.258 \times 10^3 \text{ L mol}^{-1} \text{ cm}^{-1}$. This value is comparable to one reported by Bottaro, Penwell, and Schmitt [20], who reported $5.207 \times 10^3 \text{ L mol}^{-1} \text{ cm}^{-1}$ (Figure 33). The extinction coefficient of ADN at 284 nm in methanol is $4.362 \times 10^3 \text{ L mol}^{-1} \text{ cm}^{-1}$. The extinction coefficient at 284 nm in acetonitrile is $3.804 \times 10^3 \text{ L mol}^{-1} \text{ cm}^{-1}$. For comparison, the extinction coefficient ϵ of KDN at 284 nm in water is $5.379 \times 10^3 \text{ L mol}^{-1} \text{ cm}^{-1}$.

Figure 33: UV spectrum of aqueous ammonium dinitramide solution. (Reprinted and modified from [20] with permission from © 1997 American Chemical Society; permission conveyed through RightsLink.)

Other sources report that the aqueous solution of ADN has a maximum of absorption at 283.5 nm with an extinction coefficient $\sigma = 5600 \pm 100 \text{ L mol}^{-1} \text{ cm}^{-1}$ [241]. Other sources [169] give the molar extinction coefficient of ADN as $6680 \text{ L mol}^{-1} \text{ cm}^{-1}$ at 214 nm and $5500 \text{ L mol}^{-1} \text{ cm}^{-1}$ at 284 nm. The nature of the shoulder at 335 nm is somewhat dubious.

All dinitramide salts are sensitive to light. Some metal salts with complexed dinitramide are very light sensitive and will decompose while the UV absorption spectrum is being measured [242, 243].

3.10.2.2 IR Absorption Spectra of Ammonium Dinitramide

The IR absorption spectra of dinitramide salts either in the solid state or in solution are dominated by the absorption bands of the dinitramide ion. In the case of ammonium or hydrazinium dinitramide, the cation also contributes to the spectra and complicates the interpretation. Therefore, if one wants to study the dinitramide ion by itself, one will analyze the alkali metal dinitramides. IR spectra are available for ADN and various alkali metal dinitramides, but here we show only multiple spectra for ADN (Figure 34 and 36) and KDN (Figure 74 in Section 9.2.1). Infrared spectra of ADN show strong IR absorptions at 1526 cm^{-1} (asymmetric stretch of NO_2 in phase), 1181 cm^{-1} (symmetric stretch of NO_2 out of phase), 1025 cm^{-1} (asymmetric stretch of N_3), 3255 cm^{-1} (H_4N^+), and 1407 cm^{-1} (H_4N^+). We are comparing IR spectra of ADN from several sources.

IR Spectra at Atmospheric Pressure

Infrared spectra of ADN at atmospheric pressure are shown in Figure 34. A similar IR spectrum is in a book on dinitramide salts [3]. The assignment of IR absorption bands of ADN was made as shown in Table 15.

Table 15: Assignment of IR absorption band frequencies of ammonium dinitramide.

Assignment	Wavenumber, cm^{-1}			
Source	Santhosh [58]	Christe et al. [244]	Shlyapochnikov et al. [210]	Oliveira et al. [245]

Figure 34: IR spectrum of ammonium dinitramide. (Reprinted and modified from [58] with permission granted by Dr. Santhosh 8-Feb-2021.)

The peak at 3124 cm^{-1} has been assigned to the valence vibration of N—H in NH_4^+ , the band at 1538 cm^{-1} is an asymmetric oscillation of N—O in NO_2 , and 1343 cm^{-1} is a symmetric oscillation of NO_2 .

The dinitramide ion IR spectrum (Figure 35) wavenumbers of a sample of ADN obtained by reaction of ammonia with dinitrogen pentoxide were in good agreement with literature data and were as follows: 1583, 1430, 1343, 1206, 1176, 1022, 953, 828, 762, and 732 cm^{-1} [44].

Figure 35: IR spectrum of ADN prepared by reaction of ammonia with dinitrogen pentoxide. (Republished and modified from [44], with permission of © 2002 John Wiley & Sons – Books; permission conveyed through Copyright Clearance Center Inc.)

There was concern that prilled ADN that was made by a two-phase emulsion process of molten ADN in paraffin oil might be contaminated by oil, but the IR spectrum of prilled ADN was essentially free of C—H and C—C bands (Figure 36).

Isotope substitution and the comparison of IR, Raman, and nuclear magnetic resonance (NMR) spectra of $^{14}\text{NH}_4^{15}\text{N}(^{15}\text{NO}_2)_2$ and $\text{K}^{15}\text{N}(^{15}\text{NO}_2)_2$ with those of natural ADN and KDN have enabled researchers not only to assign absorption bands to specific vibrations in designated parts of the molecule but also to predict spectra from theoretical quantum mechanical force-field calculations and normal-coordinate analyses [211]. The geometry, harmonic vibrational frequencies, and IR and Raman intensities of the dinitramide anion were calculated within DFT approximations. Figure 37 gives a comparison of the IR spectra of natural ADN and the analog compound made with $^{15}\text{N}(^{15}\text{NO}_2)_2$ anions.

Similar spectra for the potassium salt are provided in the same reference but are not shown here. Due to the structural variability of the $\text{N}(\text{NO}_2)_2^-$ anion observed in the solid state, a reliable interpretation of the IR and Raman spectra of its salts becomes much more difficult in comparison to the interpretation of spectra from solutions of

Figure 36: IR spectrum of recrystallized prilled ADN. (Republished and modified from [105], with permission of John Wiley & Sons – Books; permission conveyed through Copyright Clearance Center Inc.)

the salts in water or acetonitrile. Vibrational spectra of the solids are dependent on the counterion present. The IR spectra were complemented by Raman spectra taken from the same samples (Section 3.10.2.3). It is possible that ADN crystals pressed into a KBr pellet (common practice for IR spectrometry) may undergo ion exchange in the solid state and that the spectrum will show some lines that are due to KDN. That is why we show spectra of both salts in this book.

Samples of ADN were synthesized starting with ammonium sulfamate as the starting reactant and nitric acid as the nitrating agent. Sulfuric acid was used as a catalyst. IR spectra were evaluated by FTIR, in the near IR region and the middle IR region (MIR) [245]. The characteristic bands used to identify ADN in the MIR were 3132 cm^{-1} (stretching of NH_4^+), 1384 cm^{-1} (bending of NH_4^+), 1537 cm^{-1} (asymmetric stretching of NO_2 in phase), 1344 cm^{-1} (symmetric stretching), 1209 and 1177 cm^{-1} (symmetric stretching of NO_2 out of phase), 1032 cm^{-1} (asymmetric stretching of N_3), 954 cm^{-1} (symmetric stretching of N_3), 828 cm^{-1} (angular bending of NO_2 in phase), 762 cm^{-1} (angular bending of NO_2 out of phase), and 732 cm^{-1} (bending of NO_2 in phase). The MIR spectrum was compared to literature data and showed good agreement. In the near IR region analysis, only a few bands were observed, at 5185 and 4672 cm^{-1} , and they are typical for the region of combined bands of compounds that hold NH groups.

IR spectra were predicted using DFT calculations in the local density approximation and compared to experimental spectra and to those obtained for ADN [214]. The lattice mode spectra of AP and ADN display similar features in the region $28\text{--}220\text{ cm}^{-1}$. AP has seven frequencies in this region, which are in good agreement with the experimental reports [246]. The modes of 103.7 and 115.2 cm^{-1} in ADN correspond to the twist of NO_2 about the N—N bond. The 260.1 and 320.2 cm^{-1} modes corresponding to the lattice vibration appear in ADN but not in AP. In the region of $400\text{--}700\text{ cm}^{-1}$, AP has four frequencies. The molecular motion of the first frequency is the symmetric bending of ClO_4 , and the motions corresponding to the following frequencies are concentrated in the asymmetric bending of ClO_4 . Similarly, ADN also has four frequencies. The molecular motion of the first frequency is the symmetric bending of $\text{N}(\text{NO}_2)_2$, and the motions corresponding to the following frequencies are concentrated in the asymmetric bending of $\text{N}(\text{NO}_2)_2$. The modes of 739.7 , 822.1 , and 938.4 cm^{-1} in and, which do not appear in AP, correspond to the asymmetric bending of $\text{N}(\text{NO}_2)_2$. The calculated frequency 739.7 cm^{-1} for ADN is consistent with the experimental value 739.0 cm^{-1} . See also [174].

In the region of $1000\text{--}1200\text{ cm}^{-1}$, AP has five frequencies of absorption [214]. The molecular motions of the first two frequencies are the symmetric stretching of ClO_4 , and the motions corresponding to the following frequencies are the asymmetric bending of ClO_4 . The calculated frequencies for AP in this region have large deviations from the corresponding experimental values. The motions of these frequencies are concentrated in the ClO_4 moieties; thus, this discrepancy may be due to intermolecular hydrogen bonding interactions present in the crystal lattice, which are not well described by DFT. ADN also has five frequencies in this region. The molecular motions

of the first two frequencies are the symmetric stretching of $\text{N}(\text{NO}_2)_2$; the motions corresponding to the following two frequencies are the asymmetric bending of $\text{N}(\text{NO}_2)_2$, and the motion to the last frequency 1154.2cm^{-1} , which agrees with the experimental value, is the symmetric stretching of NO_2 . The modes of 1292.6 and 1311.8cm^{-1} in ADN correspond to the symmetric stretching of NO_2 . In the region of $1400\text{--}3300\text{cm}^{-1}$, the motion modes of NH_4 in AP and ADN present similar features. The motion of the first frequency involves the asymmetric bending of NH_4 , whereas those of the next two frequencies are concentrated in the symmetric and asymmetric stretching of NH_4 , respectively. The modes of 1706.6 and 1708.5cm^{-1} in ADN correspond to the asymmetric stretching of NO_2 . From the low-frequency to the high-frequency region, ADN has more motion modes for the vibrational frequencies than AP. The motions of the NO_2 groups in ADN are diffusely distributed. Since the torsional motions of the molecule's functional groups are usually supposed to be highly coupled to the other moiety of the molecule, it is possible that the torsion motions of the NO_2 groups act as doorways through which kinetic energy can flow into the molecule from its surroundings.

Although free dinitramidic acid is unstable and never used as such, it is of interest to compare the IR spectra of the free acid to that of the ammonium salt. The question about the free acid was whether it exists predominantly in the N–H form or the aci form with an intramolecular hydrogen bond (indicated by a dotted line) [212].

Depending on whether it is liberated from a salt in non-polar, water-free solvents or extracted from an acidified aqueous solution of KDN, the free dinitramidic acid may show different absorption spectra in the UV and the IR. Instead of a cyclic aci form with a hydrogen bond (dotted line in structure above), the proton may be shared equally between the two oxygen atoms.

Two different routes for making ADN were tested and their efficiency evaluated by IR spectroscopy [247]. One sample was made from sulfamic acid with a 40/20 ratio of WFNA/ H_2SO_4 at 243 to 238K (-30 to -35°C), and another sample was made from ammonium sulfamate at 238 to 236K (-35 to -37°C). The ADN was adsorbed on activated charcoal and desorbed with acetone. Analyzing the products by IR spectroscopy revealed some AN as a contaminant and potential decomposition product. This paper is very useful because it also contains the IR spectra of the starting reagents, sulfamic acid and ammonium sulfamate, so that their unwanted presence in the products can be identified by comparison. The product from the sulfamic acid process was of better quality than the product of the ammonium sulfamate process. The characteristic

Figure 38: Infrared spectrum of ADN prepared from sulfamic acid 40/20 in comparison to a reference spectrum. (Reproduced and modified from [247].)

bands employed to identify ADN in the MIR were 3129 and 1384 cm^{-1} (NH_4^+); 1537, 1344, 1209, and 1177 cm^{-1} (NO_2); 1032 and 954 cm^{-1} (N3); 828, 762, and 732 cm^{-1} (NO_2). The near infrared analysis pointed out few bands at 5185 and 4672 cm^{-1} . Figure 38 is a comparison of the product from the sulfamic acid 40/20 process with a literature reference spectrum. The results showed excellent agreement between the two spectra.

IR Spectra at Very High Pressures

Raman and FTIR spectra for ADN crystals were measured as a function of pressure in an LN_2 hydrostatic medium [174]. No detectable changes were observed in spectra collected below 1.6 GPa or above 2.8 GPa. In the infrared spectra, significant pressure broadening was observed, which masked any potential subtle spectral changes due to the $\alpha \rightarrow \beta$ transformation.

Assignments for the observed Raman modes are as follows: The 1174 and 739 cm^{-1} shift modes correspond to the $-\text{NO}_2$ symmetric stretch and the rocking modes of the dinitramide anion.

IR Spectra of ADN Decomposition Products

The vapor space over ADN at 333–383 K (60–110 $^\circ\text{C}$) was pumped and condensed into a matrix of frozen argon for IR absorption spectra measurement [248]. The matrix spectrum had 22 absorption bands, which all seemed to be associated with one and the

same species, namely dinitraminic acid $\text{HN}(\text{NO}_2)_2$. UV irradiation of the matrix destroyed the species, and instead a new set of absorption bands was formed, which were assigned to *trans*- HNO_2 , N_2O , NO , and $(\text{NO}_2)_2$. There was no evidence for the aci form of $\text{HN}(\text{NO}_2)_2$ in the form of $\text{N}(\text{NO}_2)\text{NOOH}$, which, according to *ab initio* calculations by other authors, was predicted to be nearly as stable as $\text{HN}(\text{NO}_2)_2$.

3.10.2.3 Raman Spectra of Ammonium Dinitramide

Raman spectra of ADN and KDN with natural abundance of ^{15}N were compared to spectra of ADN and KDN made from ^{15}N -enriched dinitramide ion ([211]; Figure 39). The spectra were also compared to spectra from the isoelectronic dinitromethane anion. Calculated and experimental IR and Raman spectra were in reasonably good agreement.

Figure 39: Raman spectra of natural ammonium dinitramide and its ^{15}N -substituted analog (dashed line). (Republished and modified from [211], with permission of © 2001 Elsevier Science & Technology Journals; permission conveyed through Copyright Clearance Center Inc.)

Earlier Raman studies of the structure of the $\text{N}(\text{NO}_2)_2^-$ anion in aqueous solution used *ab initio* calculations to interpret the measured spectra [244]. Measured spectra (Figure 40) agreed reasonably well with the harmonic vibrational frequencies calculated for the most stable C_2 conformation. However, the polarization properties of several Raman lines in ADN solutions (Figure 41) forced the spectroscopists to reduce the symmetry of the $\text{N}(\text{NO}_2)_2^-$ anion in solution to a C_1 conformation (i.e., no symmetry). This was attributed to the very small (< 3 kcal/mol) $\text{N}-\text{NO}_2$ rotational barrier in $\text{N}(\text{NO}_2)_2^-$, which allows for easy deformation. This was in contrast to theories by other investigators who had proposed a C_2 symmetric structure based on IR and Raman spectra [210].

The vibrational and electronic IR and Raman spectra of dinitramide salts $\text{MN}(\text{NO}_2)_2$ [$\text{M} = \text{K}, \text{Na}, \text{Li}, \text{NH}_4, \text{Fe}, \text{Ag}, \text{Mn}, \text{Mg}, \text{Rb}, \text{or } \text{C}(\text{NH}_2)_3$] as solutions and melts were interpreted from the anion model with the C_{2v} symmetry [249]. The complication of the spectra in the crystalline phase was explained by a restructuring of the anion, which reduces its symmetry and makes the nitro groups nonequivalent. Table 16 is a compilation of the Fourier transform (FT)–Raman peak assignments for ADN.

FT-Raman spectroscopy employing near IR laser radiation at a wavelength of $1.064\text{ }\mu\text{m}$ (9394.5 cm^{-1}) as the light source was used to characterize ADN and several propellant formulations [250]. Raman spectra were measured over the region from 75 to 3000 cm^{-1} , relative to the laser line.

3.11 Electrical Properties of Ammonium Dinitramide

3.11.1 Dipole Moment of Ammonium Dinitramide Crystals

The hybridization of the central nitrogen of the dinitramide ion is sp^2 -like, as observed in the two biguanidinium salts $[(\text{NH}_2)_2\text{C}_2\text{N}][\text{N}_3\text{O}_4]$ and $[(\text{NH}_2)_2\text{C}_2\text{NH}][\text{N}_3\text{O}_4]_2$. Despite this robust topology, the dipole moment obtained from both experiment and crystal modeling is larger than that computed for a single dinitramide ion [196]. Significant differences in the direction of the dipole from theory and experiment were found, as were differences in the atomic charges. Strong hydrogen bonding polarizes the dinitramide ion, increasing the negative charge on the most strongly hydrogen bonded oxygen atom. Decomposition of the theoretical molecular dipole moment into atomic charge and atomic dipole contributions revealed that the atomic dipoles are nearly equal in both the crystal and single molecular ion. Changes in the atomic charge contribution to the molecular dipole moment principally account for the induced dipole.

3.12 Magnetic Properties of Ammonium Dinitramide

Nuclear magnetic resonance (NMR) spectra of ADN dissolved in D₂O were measured under high-resolution conditions with an NMR spectrometer at 400.13 MHz proton resonance frequency [251, 252]. In the same series of NMR measurements, HNIW shifts were compared to those of ADN. The ¹⁴N, ¹⁵N, and ¹⁷O NMR spectra of ADN were measured, and the signals were assigned to specific parts of the molecule. The chemical shifts are tabulated in Table 17. The atom highlighted in **bold** is the atom to which the shift was assigned. Because of proton/deuteron exchange, the ¹H spectrum of ADN could not be measured. The ¹⁴N spectrum in ADN has three lines, at $\delta = -12$ (nitro group), at $\delta = -60.2$ (central amino N), and at $\delta = -360.1$ (NH₄⁺ ion). As opposed to ¹⁴N NMR signals, the ¹⁵N atom gives very sharp lines, but due to the low natural abundance of this isotope, the scanning times are very long before one has a good spectrum. Three ¹⁵N lines were seen, one of which ($\delta = -60.8$, broadened) belongs to the amino nitrogen, the other ($\delta = -12.2$) belongs to the nitro group, and the last ($\delta = -360.1$) belongs to the nitrogen in the ammonium ion.

Table 17: NMR chemical shifts of ADN.

Nucleus	MHz	Shift, ppm	Assignment
¹⁴ N	28.91	-12.0	(N- NO ₂) $\Delta 1/2 = 12.4$ Hz
		-60.2	(N -NO ₂) $\Delta 1/2 = 940$ Hz
		-360.1	(NH ₄ ⁺) $\Delta 1/2 = 4.5$ Hz
¹⁵ N	40.56	-12.2	N- NO ₂
		-60.8	N -NO ₂
		-360.1	(NH ₄ ⁺)
¹⁷ O	54.24	469.6	(N- NO ₂) $\Delta 1/2 = 204$ Hz

Data source: [252]

A thorough examination of the IR and Raman spectra of ADN and KDN solids and the dinitramide ion in solution had already provided a fairly accurate description of the molecular structure of the three species [211]. These measurements were supplemented by NMR spectra of KDN in acetone-D₆. Three of the six possible isotopomers of the N(NO₂)₂⁻ anion, those with a ¹⁵N in the middle, represent the majority of the species seen in the NMR spectra (Figure 42). In the ¹⁵N NMR spectrum of KN(NO₂)₂ the most pronounced splitting patterns are a doublet at $\delta = -9$ ppm and a triplet at $\delta = -55$ ppm. They correspond to the ¹⁵N resonances of nitro groups in O₂¹⁵N-¹⁵N-¹⁴NO₂ and O₂¹⁵N-¹⁵N-¹⁵NO₂ (doublet) and to the central nitrogen atom in O₂¹⁵N-¹⁵N-¹⁵NO₂ (triplet).

4 Chemical Properties of Ammonium Dinitramide

4.1 Reactions of Ammonium Dinitramide

4.1.1 Acid Strength of Hydrogen Dinitramide

Dinitramine (“dinitramidic acid,” hydrogen dinitramide) is one of the strongest inorganic acids, and therefore it can form salts not only with strong but also with weak bases. The $\text{p}K_{\text{a}}$ of dinitramidic acid is -5.62 , compared with -0.9 for nitric acid. It is thus a stronger acid than nitric acid or sulfuric acid and is weaker only in comparison to hydrochloric acid and perchloric acid.

Depending on the acidity of the solution, dinitramide is present in three different forms: $\text{N}(\text{NO}_2)^-$ anions, neutral $\text{HN}(\text{NO}_2)_2$ molecules, and protonated $\text{H}_2\text{N}(\text{NO}_2)_2^+$ cations. The rate of the thermal decomposition of dinitramide solutions is dependent

on the acidity of the solution. The temperature dependence of the equilibrium constant of dissociation (acidity constant) of $\text{HN}(\text{NO}_2)_2$ (K_a) is [253]:

$$K_a = 1.4 \times 10 \exp\left(-2.6 \times \frac{10^3}{T}\right)$$

The temperature dependence of the equilibrium constant of the dissociation of the protonated dinitramide $\text{H}_2\text{N}(\text{NO}_2)_2^+$ is:

$$K_{a\text{-protonated}} = 1.1 \exp\left(6.4 \times \frac{10^3}{T}\right).$$

4.1.2 Acid Resistance of Dinitramide and Dinitramide Salts

Dinitramide salts are stable to base but slowly decompose in concentrated acids at room temperature [164].

Because dinitramide and dinitramide salts are often synthesized in acidic solutions, the yield of the desirable products is limited by simultaneous premature decomposition of the product due to the acidic medium. In a reacting mixture, there is a dynamic equilibrium concentration of dinitramide that peaks out and then disappears altogether if the reaction is not terminated at an opportune time. In 8-M H_2SO_4 , no loss is seen after 8 h, but in 11-M and above, the decomposition is quite rapid. Similarly, the decomposition in concentrated HNO_3 is found to be fast in 70% HNO_3 and above, and it is slow in HNO_3 treated with urea. Urea destroys the nitrous fumes in WFNA. The oxides of nitrogen in the untreated HNO_3 catalyze the decomposition of dinitramide. Dinitramide is hydrolyzed by acids [254]. The rate of this reaction was measured by spectrophotometry in aqueous H_2SO_4 , HClO_4 , and HNO_3 solutions over a wide temperature range and at various compositions of the medium. On the basis of the dependence of the apparent rate constants on the composition of the medium and of the UV spectra of solutions of nitramide NH_2NO_2 in concentrated nitric acid and its mixtures with H_2SO_4 , a mechanism was proposed for the acid-catalyzed decomposition of dinitramide. The proposed mechanism includes denitration of dinitramide to nitramide and nitronium cation; the subsequent decomposition of nitramide yields nitrous oxide and water:

Depending on the nitrating power of the medium, the rate-determining stage may be either denitration of dinitramide or decomposition of nitramide.

The half-life times of ADN at different temperatures in sulfuric acid solutions of different strengths are listed in Table 18.

Table 18: Decomposition of ADN in sulfuric acid solutions.

Acid concentration	Temperature		Rate constant	Half-life, $t_{1/2}$
	K	°C	min ⁻¹	min.
6.3M	303	30	No decomposition	—
6.3M	323	50	0.0003	2310.5
6.3M	338	65	0.0005	1386.3

13M*	303	30	0.335	2.1

From [58], except those data marked with an asterisk*, which are from [20]

Dinitraminic acid is a colorless unstable liquid that decomposes to give HNO_3 and N_2O . Dinitraminic acid is the most acidic acid among the known gas-phase acids [255]. The gas-phase acidity of dinitramidic acid was found to be $\Delta H^\circ_{\text{acid}} < 1297 \text{ kJ/mol}$ ($< 310 \text{ kcal/mol}$). Dinitramide anion is extremely unreactive in the gas phase and is a poor nucleophile. It does not react with O_2 , CO_2 , CS_2 , or SO_2 .

4.1.3 Reactions of Dinitramides with Inorganic Substances

The main reactions of dinitramides with inorganic substances are those with metals with high heats of combustion, which are often added to solid propellants to increase performance and to reduce the tendency to combustion instabilities. Other mixtures of dinitramide oxidizers (mostly alkali metal dinitramides) and metal powders have also been proposed for pyrotechnic igniters.

Most solid propellants contain metals as a means to increase the energy output. Metal oxides have highly negative enthalpies of formation and high heats of combustion. If advanced solid propellants are formulated with ADN and metals, one needs to know the potential for premature reactions between ADN and metals during propellant processing and storage. Interaction between ADN and metals, in particular Be, Mg, B, and Al, can be determined by experiment or can be predicted by quantum chemical density-functional theory (DFT) model calculations [256]. The results indi-

cate that Be and Mg are oxidized by ADN in close contact but that B and Al are not. In the case of Be and Mg, the reduction of ADN is accompanied by the removal of NO_2 moiety, which has negative total charge. On the other hand, the interaction pattern of these elements with dinitramidic acid in the presence of ammonia is different from the ADN + metal reaction.

An unusual synthetic application of dinitramide salts is the controlled stage-by-stage substitution of fluorine atoms with oxygen in interhalides [257]. In these reactions, the $\text{N}(\text{NO}_2)_2^-$ anion is preferable to the nitrate that has been used in other cases. For example, $\text{KN}(\text{NO}_2)_2$ smoothly reacts with BrF_5 at 228 K (-45°C) to quantitatively give KBrOF , N_2O , and FNO_2 , and its interaction with ClF_5 at 260 K (-13°C) yields an equimolar mixture of KClOF_4 and KClF_4 . It is remarkable that KClOF_4 is formed as an intermediate product because with most other exchange reagents, e.g., NO_3^- , it is difficult to terminate the process in this stage, and FCIO_2 is the only product.

4.1.4 Reactions of Dinitramides with Organic Substances

The main concern about reactions of dinitramides with organic substances is about those occurring prematurely with binders and curing agents during the production of solid propellants [258]. After the propellant is cured, other reactions, often undesirable, continue at a slow rate at room temperature and cause the propellant to age more rapidly. Reactions of ADN with binders and curing agents will be discussed in a future volume on solid propellants. Other organic reactions are discussed here.

It was difficult to find suitable curing agents for ADN-based solid propellants because dinitramide reacted with many isocyanates commonly used in the past to cure AP-based propellants.

The reactivity of dinitramide and its aci-isomer (if it exists) toward alkenes was theoretically studied using electron density functional B3LYP/6-31+G(d,p) and non-empirical *ab initio* CBS-QB3 methods [259]. It was concluded that the rate of 1,3-dipolar cycloaddition to the double bond of the N—N—O fragment is comparable to the rate of interactions of nitrile oxides and azides with olefins but that *I* decreases in the presence of electron-acceptor substituents at the double bond. The observed reactivity trends support the design of unsaturated compounds that are highly reactive toward azides and chemically inert toward dinitramides. This may be helpful for the development of binders for ADN-based propellants.

Combustion reactions of ADN with organic binders and additives as they will occur in solid propellants in a rocket motor will be described in a future volume. Several combustion experiments were conducted with ADN and a combustible solid (binder, binder surrogate) sandwiched together with or without a gap between the two reactants. Section 4.11.2.1 ("Experimental Study of ADN Combustion in Model Solid Propellants") contains some information on combustion reactions of ADN with polymeric binders in model propellants.

The interaction and compatibility of ADN with various propellant compositions, including binders, curing agents, plasticizers, and energetic fillers, were investigated by means of pressurized differential scanning calorimetry (PDSC) [260]. Results showed that the onset of decomposition temperature of ADN/polyethylene glycol (PEG)/toluene diisocyanate (TDI) and ADN/PEG/hexamethylene diisocyanate (HDI) mixtures was 16–26°C lower than that of ADN by itself. The interactions between them are dangerous, and ADN is incompatible with PEG, TDI, and HDI. The decomposition temperature of ADN-NG/butanetriol trinitrate (BTTN), ADN-TEGDN, ADN-Bu-NENA, and ADN-HMX mixtures was 0.5–7.5°C higher than that of ADN. The difference of decomposition temperatures of ADN-glycidyl azide polymer (GAP), ADN-PBT, ADN-PET, ADN-IPDI, ADN-N-100, ADN-NG, ADN-trimethylolethane trinitrate (TMETN), ADN-BDNPA-F, and ADN-Al mixtures was less than 2°C, and ADN should be compatible with those compositions.

4.1.4.1 Reactions of Dinitramides with Nitrate Esters

Nitrate esters are contained in double-base propellants and many energetic plasticizers. ADN may or may not be compatible with nitrate esters.

The thermal stability and safety properties of two ADN-based propellants containing different relative amounts of ADN crystals, TMETN, 1,2,4-BTTN, and GAP were measured by differential scanning calorimetry (DSC), TGA-FTIR, and accelerating rate calorimetry (ARC) [165, 261].

The interactions of double-base propellant ingredients nitrocellulose and nitroglycerin (NC/NG) with ADN were investigated by PDSC, thermogravimetry-derivative thermogravimetry (TG-DTG), and a vacuum stability test (VST) [262]. The results showed that the decomposition exothermic peak temperature of NG in the NC/NG is 480 K (207°C), but it drops to 433 K (159.8°C) in the (NC/NG)/ADN system at atmospheric pressure and drops further to 427 K (153.6°C) at higher pressure. It was shown that ADN is less compatible with NC than with NG. The rate of gas evolution of ADN/NC/NG as evaluated by VST was excessive.

The interaction of ADN and mixtures of NC and NG at high temperatures was investigated by a gasometric method [263]. Results showed that compared with the sum of the maximum standard volume of evolved gas from ADN and (NC + NG) systems, the maximum standard volume of evolved gas from the ADN/(NC + NG) mixture (626.8 mL/g) decreased, but the decomposition rate evidently increased, and the activation energy decreased to 82.58 kJ/mol, which showed that there is a strong interaction between ADN and (NC + NG).

On the basis of the study of thermal behavior of ADN and the interaction between ADN and NC, the influences of stabilizers, such as *N*-methyl-*p*-nitroaniline (MNA), 1,3-dimethyl-1,3-diphenylurea (Centralite 2 = C2), 2-nitrodianiline(2-NDPA), hexamethylenetetramine (HMT), and mixtures of MNA/C2, MNA/2-NDPA, and MNA/HMT, on the nascent interactions between ADN and NC were investigated by DSC [264]. The results showed that the interaction between ADN and NC can be decreased to

a certain extent by mixing MNA and C2, and the nascent interaction between ADN and NC can be inhibited by mixing the complex of MNA/C2, MNA/2-NDPA, and MNA/HMT. Comparing the binary system of ADN/NC, the value of ΔT_p , which is the DSC exothermic peak temperature difference between ADN/stabilizer and NC, can be decreased from 19.2 to 11.9 degrees by using the mixtures of stabilizers.

4.2 Photolysis of Ammonium Dinitramide

All dinitramides are sensitive to light and are best stored in the dark.

4.2.1 Photolysis of Solid Ammonium Dinitramide

Prilled ADN was photolyzed by exposure to sunlight and was analyzed by IR, and the purity and apparent storage life of photolyzed ADN were tested by high-performance liquid chromatography (HPLC) [265]. Photolysis products are NO_3^- , NO, N_2O , and N_2 , along with small amounts of NO_2^- . The results indicated that the primary solid product of ADN photolysis is AN, and the apparent storage life of ADN photolyzed with sunlight is 756 d. Further decomposition of ADN is restrained because ADN grains are coated by the AN formed as photolysis product.

4.2.2 Photolysis of Ammonium Dinitramide Solutions

ADN solutions were kept in side-by-side clear and amber glass bottles, and samples were taken periodically and analyzed [58]. The decay of ADN as a function of time is shown in Figure 43 for three solutions with three different starting concentrations. Solutions in clear glass bottles decomposed much faster than those kept in amber glass bottles.

Solutions of ADN in water are sensitive to light. While the sensitivity to light may complicate the handling and storage of ADN in the laboratory and may affect the storage life of formulated propellants, this is a blessing in disguise because if ADN is accidentally spilled into surface waters, it decays under the influence of sunlight before it can do much environmental damage.

In the wake of the realization that AP production wastes and accidental spills from AP fires are quite persistent in the environment and that AP contamination had found its way into agricultural products and drinking water, the environmental chemistry of ADN was investigated in detail to make sure that ADN, a potential AP replacement, would not cause the same problems downstream. As part of such a study, the photolysis of ADN in natural waters was analyzed and modeled [266, 267]. Dark solutions of ADN were stable indefinitely, and indirect photolysis did not provide a significant decay mechanism. Photolytic rate constants for the photolysis of ADN were determined in order to better understand the fate of ADN in natural bodies of water. Quantum

Figure 43: Decomposition of ADN solutions stored in clear and amber glass bottles. (Reprinted and modified from [58] with permission granted by Dr. Santhosh 8 February 2021.)

yields were measured between 290 and 400 nm using a filtered light system, and these values were combined with absorption of light in a water column to model photolysis rates as a function of water depth. The validity of this model was tested in field trials in Onondaga Lake, Syracuse, New York, USA. For summertime irradiation, half-life times ranged from ~6 min at the surface to ~15 years at a depth of 2 m. The predicted and observed degradation rates of ADN were quite similar. It was also found that the degradation of ADN was not enhanced to any measurable degree by sensitized photoreactions in humic solutions.

Free-radical and thermal and photolytic decomposition products of ADN were compared to those of cyclic nitramines and AP [268]. Photochemical formation of NO_2 by UV photolysis of ADN at 77 K followed first-order kinetics, whereas photolysis of cyclic nitramines (RDX, HMX, HNIW) formed NO_2 via zero-order reactions. If ADN is caused to decompose thermally at 463 K (190 °C), free radicals can be trapped by radical scavengers and identified by electron spin resonance (ESR) [269].

ADN in aqueous solution absorbs light in the UV region and decomposes photolytically to form nitrate ion, nitrite ion, and nitrous oxide [270]. The rate of photolysis and the product distribution are dependent on the pH of the solution. At pH 11, the ratio of $\text{NO}_2^-/\text{NO}_3^-$ is about 20, but at pH 2, the ratio is only 0.5. Dilute (10–50 μM) ADN solutions in water have a half-life time of ~3–4 min in sunlight.

4.3 Electrolysis of Ammonium Dinitramide

The electrolysis of ADN does not result in formation of tetranitrodiazane ($(\text{NO}_2)_2\text{NN}(\text{NO}_2)_2$), which is unstable and unknown. The electrolysis of ADN in dimethyl sulfoxide (DMSO) was studied by cyclic voltammetry trials with a platinum electrode [271]. The associated mechanisms were predicted based on a quantum chemical calculation. ADN exhibited three redox peaks at -0.69 , -1.16 , and -1.52 V, and two oxidation peaks at 0.34 and 0.50 V (vs Ag/AgCl) at a scan rate of 50 mV/s. Quantum chemistry calculations identified possible pathways for the electrolysis of ADN in DMSO and indicated that reduced ADN rapidly decomposes to form NH_3 , N_2O , NO_2 , and OH^- .

4.4 Analysis of Ammonium Dinitramide

Because ADN is very sensitive to contamination, it is important to have accurate analysis methods to determine the types and quantities of contaminants that might reduce the thermal stability of this rocket propellant oxidizer.

ADN is intended as a replacement for AP, which has been the cause of widespread drinking water pollution. In order to make sure the same will not happen again with ADN spilled and leaked into the groundwater, sensitive methods have been developed to analyze for traces of ADN in the wastewater leaving the propellant processing plants.

4.4.1 Volumetric Analysis Methods for Ammonium Dinitramide

A rapid and simple method to determine the purity of ADN is non-aqueous potentiometric titration [272]. A quaternary ammonium salt was used as the titrant, while AN, the major impurity present in ADN that tends to cause serious interference, was removed. The standard deviation of the method was 0.001 g, and its coefficient of variation was 0.19% .

4.4.2 Spectroscopic Analysis Methods for Ammonium Dinitramide

Nitrate and nitrite ion are common contaminants in ADN and need to be tightly controlled to prevent instability of the propellant products. UV spectrophotometric methods can give only a partial answer [273]. ADN and other energetic additives in solid propellants can be detected and quantified by laser Raman spectroscopy [250].

At the time when the propulsion community became aware of widespread contamination of groundwater by perchlorate, there was a need for sensitive perchlorate ion analysis. It is unlikely that dinitramide will ever become an environmental contaminant like the perchlorate it is intended to replace, but sensitive analysis methods are now available for dinitramide analysis in water. This method converts the

dinitramidate to nitrite by UV photolysis and determines the nitrite by reaction with 4-aminothiophenol and *N*-(1-naphthyl)ethylene diamine, forming an azo dye that can be determined colorimetrically [274].

4.4.3 Chromatographic Analysis Methods for Ammonium Dinitramide

Anionic impurities in ADN can be analyzed by either ion chromatography with UV detection [275] or capillary ion electrophoresis with UV detection [276]. The presence of ADN in the IC eluent can be detected by its UV absorption at 214 nm. The disadvantage of UV detection is that sulfate ions cannot be detected this way because they do not absorb light in the UV. The analyses could be completed in <20 min or <6 min, respectively. For capillary ion electrophoresis, Oehrle [276] used a chromate and a phosphate electrolyte. In this case, dinitramide ion was measured at 254 and 185 nm. Good separation of ADN and its degradation products was achieved with the phosphate electrolyte. An example of dinitramide/nitrate separation by capillary ion electrophoresis is shown in Figure 44, where the small peak on the left is nitrate and the large main peak is dinitramide.

Figure 44: Analysis of nitrate and dinitramide by capillary ion electrophoresis. (Reprinted and modified from [58], with permission from Dr. Gopalakrishnan Santhosh granted 8 February 2021.)

For evaluating the purity of the synthesized and/or treated or aged pure or formulated ADN, the AN content needs to be known. AN is known to be a by-product of ADN synthesis as well as a possible decomposition product of ADN. Heated ADN decomposes mainly to N_2O , H_2O , NO_2 , and AN, which further reacts to N_2O and NH_3 . Determining only the nitrate contents, assuming the rest to be intact ADN, will not lead to correct

values because there may be other contaminants. Depending on how it was made, another possible contaminant in ADN is ammonium nitrourethane (ANU), which is an intermediate in the production of ADN from urethane. The ANU concentration carried over into the product must be kept as low as possible. Therefore, a quick and accurate method for detecting nitrourethane besides nitrate and dinitramide is needed.

The best method is an IC method for the direct analysis of all anions concerned [277–280]. The IC instrumentation (Alltech/GAT) used at the ICT was a so-called single-column ion chromatography (SCIC) technique that used no suppressor in combination with the electrical conductivity detector. Here the ground level of the conductivity of the used eluent is compensated electronically. Alternative systems using the suppressor technique reduced the ground conductivity of the eluent, chemically yielding to a greater usable detection range of the detector. For standard anions, cations, and organic acids, the SCIC system has been a well-suited technique making measurements possible at the ppm or even the ppb level. Different ion exchanger phases were tested in the IC columns with organic and/or inorganic eluants. Best results were obtained with a special IC anion exchange column from DIONEX (IonPac 11 HS) in combination with the UV detector. This separation phase could be used with sodium hydroxide as the eluent also at very high concentrations. Moreover, NaOH shows essentially no UV absorption in the possible wavelength region. The ionic strength and flow rate of the eluant was optimized to get an acceptable resolution for nitrite and nitrate combined with a short run-time for the whole analysis. Detection was either by electrical conductivity or UV absorption, whereby the UV measurement wavelengths were tuned in order to get a small signal-to-noise ratio and simultaneously a suitable sensitivity (especially for NO_3^- and nitrourethane). The UV detector was adjusted at 214 nm for the analysis of NO_2^- and NO_3^- and at 285 nm for the detection of dinitramide. Limits of detection (LOD) of 0.05 to 0.01 ppm were realized for NO_3^- and NO_2^- , respectively, measured at 214 nm. Using 220 nm as the detection wavelength resulted in a worse LOD of about 0.3 ppm for nitrate. Using a wavelength between 210 and 220 nm resulted in an LOD for ADN of about 1 ppm. The linearity range for the analysis of dinitramide anion (at 285 nm) was found to be very broad (up to 700 ppm). All anions could be analyzed at the same time in one run, taking no more than 30 min.

An HPLC-UV method has been developed for the analysis of dinitramide and the anionic impurities nitrate and nitrite in commercial ADN [281]. All of these anions can be analyzed on a porous graphitic carbon column.

ADN crystals and prills were analyzed by IC [165]. Three different measurements were performed on each sample: **(1)** cation analysis (Na^+ , K^+ , NH_4^+), **(2)** trace anion analysis (NO_3^- , SO_4^{2-} , Cl^- , NO_2^-), and **(3)** dinitramide ion analysis. A Dionex DX-600 IC and a Dionex DX-320 IC, both equipped with conductivity detectors, were used for the cation and the trace anion analysis, respectively. For the selective measurement of dinitramide, a Dionex AD25 UV absorption detector was used in addition to the conductivity detector. Na^+ , K^+ , and NO_3^- were detected in both ADN samples. Trace amounts of SO_4^{2-} but no Cl^- or NO_2^- were found in the crystals.

Analysis of ADN in pure form as well as in mixtures can be carried out by IC [282]. The purity of ADN was directly determined by estimating the dinitramide ions and indirectly by estimating the impurities. Both methods gave results comparable with those determined by DSC and UV spectroscopy. The chemical composition of ADN in mixtures containing nitrate, chromate, chlorate, perchlorate, and thiocyanate ions was quantitatively estimated in the same solution without any interferences or prior separation of analyte ions. The ion chromatographic methods for the analysis of ADN are simple and fast, with good accuracy and precision compared to other wet chemistry analytical techniques. The IC methods were found to be highly suitable for quality-control analysis of ADN containing compositions and for the online process monitoring of the formation of ADN in the reaction mixture.

The purity of ADN was determined by an HPLC method using an Agilent C18 column (150×4.6 mm, $5\mu\text{m}$) at 303 K (30°C) with acetonitrile-phosphoric acid as the binary mobile phase with a pH value of 3.0 (volume ratio 10:90) at a flow rate of 1.0 mL/min. and UV detection wavelength of 210 nm [283]. Results showed that when the concentration of ADN was in the range of 0.1–1 mg/mL, there was a linear relationship between the peak area of the chromatogram and ADN concentration: $A = 51.73C + 5.442$. The linear correlation coefficient was 0.9980, average recoveries were 98.33–99.67%, and the relative standard deviation was $\pm 0.49\%$.

The performance and durability of ADN as an oxidizer in rocket propellant compositions depend on its purity. The presence of undesired impurities would be detrimental to its performance and storability. During ADN production, the overall yield of the product depends on the purity of the precursors. Hence, it becomes essential to analyze both the precursors and the final product using suitable analytical techniques prior to application in propellant compositions. ADN and its precursors such as guanylurea dinitramide (GUDN) and potassium dinitramide (KDN) were characterized using UV/visible, FTIR spectroscopy, and DSC [284]. The ions involved in GUDN, KDN, and ADN were analyzed using IC for the direct analysis of anions and cations. The compounds were also characterized using atomic absorption spectrometry to estimate their purity.

4.4.4 Mass Spectrometric Analysis Methods for Ammonium Dinitramide

ADN sublimation and dissociation have been investigated using high-energy xenon atoms to sputter ions directly from the surface of the neat crystalline solid [285]. Tandem mass spectrometric techniques were used to study dissociation pathways and products of the sputtered ions. Among the sputtered ionic products were NH_4^+ , NO^+ , NO_2^- , N_2O_2^- , $\bullet\text{N}_2\text{O}_2^-$, N_3O_4^- , and an unexpected high abundance of NO_3^- . Tandem mass spectra of the dinitramide anion revealed the uncommon situation in which a product ion (NO_3^-) is formed in high relative abundance from metastable parent ions but is formed in very low relative abundance from collisionally activated parent ions. It was proposed that the NO_3^- anion is formed in the gas phase by a rate-determining

isomerization of the dinitramide anion that proceeds through a four-centered transition state. The formation of the strong gas-phase acid, dinitraminic acid (HN_3O_4), the conjugate acid of the dinitramide anion, was observed to occur by dissociation of protonated ADN and by dissociation of ADN aggregate ions with the general formula $[\text{NH}_4(\text{N}(\text{NO}_2)_2)_n]\text{NH}_4^+$, where n was 1 to 30.

4.4.5 Electrochemical Analysis Methods for Ammonium Dinitramide

A graphene modified glassy carbon electrode (GMGCE) was developed to investigate the electroreduction of ADN using cyclic voltammetry and differential pulse voltammetry techniques [286]. ADN was reduced with higher rates at low potentials on GMGCE compared to GCE. The GMGCE exhibited fast response toward ADN with a detection limit of 2.0×10^{-6} M and a linear range of 2.5×10^{-6} to 8.5×10^{-4} M. The possible interference from several common ions was tested, and the method was successfully applied in the determination of ADN in water samples.

4.5 Thermal Stability and Decomposition Reactions of Ammonium Dinitramide

ADN may decompose at elevated temperatures in the solid (crystalline), molten (liquid), vapor (sublimed), and dissolved states. The mechanisms may be different depending on what the environment of the molecules is like. The study of the thermal stability of ADN includes experiments in the laboratory, development of kinetic models to fit the experimental data, and *ab initio* molecular dynamics calculations from scratch to predict the thermal stability of ADN and other nitramines without ever getting one's hands dirty.

All energetic compounds decompose slowly, although the more stable ones decompose only immeasurably slowly. What separates a potentially useful energetic oxidizer from one that is not is the rate at which the transformation occurs, or the kinetic stability. Quantum chemical studies are a useful tool in predicting decomposition rates and should precede synthetic efforts. Ideally, a high-energy-density material (HEDM) suitable for safe handling at room temperature should have a free-energy activation barrier for decomposition that exceeds 125 kJ/mol (30 kcal/mol). This value is estimated assuming first-order decomposition kinetics and corresponds to a half-life of 35 years at room temperature. The thermal decomposition of ADN and its parent acid and its anion can be predicted based on quantum mechanical calculations (see later paragraphs).

The first publications referenced in the following section contain information on thermal decomposition of ADN. The first sections in the following chapter discuss just the thermal effects without any chemistry involved. Subsequent sections will not only discuss the thermal effects but will also analyze the intermediates involved in the reaction leading to the ultimate decomposition products. It was suggested that the chemical transformation of ADN during decomposition and combustion includes two main

pathways (mechanisms): an ionic heteropolar pathway and a dissociative homopolar pathway.

ADN is less stable thermally than KDN, but it is much more stable than NH_4NO_2 and alkyl dinitramides ($\text{R}-\text{N}(\text{NO}_2)_2$). Among ammonium salts, the order of anion stability is

The higher stability of $\text{N}(\text{NO}_2)_2^-$ is attributed to stabilization of the overall negative charge through the electron resonance effect. The thermal stability of dinitramide metal salts depends on the metal cation electronegativity, thus the higher electronegativity results in a higher decomposition rate. In dinitramide onium salts, such as hydrazinium, guanidinium, anilinium, and tetramethylammonium dinitramide, basicity of the cation strongly influences the decomposition rate [287]. Salts of bases with $\text{p}K_a < 5$ have an order-of-magnitude greater decomposition rate than bases with $\text{p}K_a > 8$.

The stability of dinitramide salts is a highly complex issue, and the experimentally determined decomposition barrier of solid-state ADN is typically reported in the range of 29–42 kcal/mol. However, the decomposition barrier for the free dinitramide anion has been theoretically estimated to be 197 kJ/mol (47 kcal/mol). The larger barrier can be attributed to stabilization of the anion through considerable electron resonance delocalization. The actual real-life stability of dinitramide anion is strongly coupled to its ability to polarize charge, and its chemical environment has been shown to be of great importance.

An excellent summary of the decomposition reactions and burning rates of ADN with 89 literature references was published by Yang in 2005 [288]. The list of references is very useful because it also gives the complete titles of the papers referenced, not only the author name and the source. The basic thermal properties, chemical pathways, and reaction products in both the condensed and gas phases were summarized over a broad range of temperature and pressure conditions. Detailed combustion-wave structures and burning-rate characteristics were compared with other types of energetic materials. In particular, the influence of various condensed-phase and gas-phase processes in affecting the pressure and temperature sensitivities of the burning rate was explained. In the condensed phase, decomposition proceeds through the reactions

and

the former mechanism being the basic one. In the gas phase, the mechanisms

and

are prevalent. The gas-phase combustion-wave structure in the range of 0.5–2.03 MPa (5–20 atm) consists of a near-surface primary flame followed by a dark-zone temperature plateau at 873–1273 K (600–1000 °C) and a secondary flame followed by another dark-zone temperature plateau at 1273–1673 K (1000–1400 °C). At higher pressures (6.08 MPa = 60 atm and above), a final flame is observed at about 2073 K (1800 °C) without the existence of any dark-zone temperature plateau. The Yang 2005 paper [288] also contains an extensive discussion of the kinetics of NO_2/NH_3 reactions, which are not included in our review.

The most detailed summary of literature on the thermal decomposition of ADN was published in 2016, and it contains all of the references offered here and even more [289]. This paper would be a valuable resource to have in everybody's library. Another excellent review of ADN thermal stability includes 102 literature references [290].

4.5.1 Thermal Stability, Decomposition Reactions, and Autoignition of Solid or Molten Ammonium Dinitramide

ADN has not been around very long, and once it became available, most of it was used up right away for characterization or burning-rate experiments. Hardly any ADN was set aside for controlled storage tests in which samples were taken about once a year to monitor the stability of the material during storage in a closed container in the dark at room temperature.

Aging can change the performance of energetic materials. Freshly synthesized ADN (ADN-2009) was compared with a sample that had been stored in the dark for 11 years (ADN-1998) [291]. Characterization was conducted using IR, Raman, and UV spectroscopy, sealed cell differential scanning calorimetry (SC-DSC), and a thermal activity monitor (TAM). The results of IR, Raman, UV spectroscopy, and SC-DSC suggested that ADN-1998 had an altered composition and was a mixture of ADN and AN, showing that some of the ADN had degraded to AN during storage. The amount of ADN in ADN-1998 was 57 mass-% in the surface region and 89 mass-% in the core region, showing that more aging had occurred on the surface than in the core region. The results of DSC and TAM analysis showed the influence of aging on the thermal decomposition of ADN. It appeared that the presence of AN generated by the aging of ADN mainly caused the difference of thermal properties.

ADN is known to degrade to AN during storage, which will affect its performance. The effects of aging on the thermal decomposition mechanism of ADN and thermal behavior of ADN and ADN/AN mixtures were studied by analyzing the gases evolved during their decomposition, using DSC, TGA-DTA-IR, and TGA-DTA-MS [292]. The results of these analyses demonstrated that the decomposition of ADN occurred via a series of distinct stages in the condensed phase. The gases evolved from ADN decomposition were N_2O , NO_2 , N_2 , and H_2O . In contrast, ADN mixed with AN (to simulate aging)

did not exhibit the same initial reaction. It was concluded that aging inhibits early-stage, low-temperature decomposition reactions of ADN. Two possible reasons were proposed, these being either a decrease in the acidity of the material due to the presence of AN, or inhibition of the acidic dissociation of dinitraminic acid by NO_3^- .

4.5.1.1 Experimental Studies of Thermal Decomposition of Condensed Phase Ammonium Dinitramide

This section deals only with the slow, controlled decomposition of ADN as it might occur in a DSC or ARC. There is also an additional section on the catalytic (as opposed to purely thermal) decomposition of ADN and ADN solutions. Another section deals with the flash pyrolysis of ADN, which is typically done by a rapidly heated filament or by laser illumination. Further down in that section is a section on the actual combustion of ADN in solid propellants and the strand burning rate of ADN. Slow decomposition of ADN is evident by the evolution of gas bubbles from the melt, which begins immediately after melting.

Initial melting of impure grades of ADN containing varying amounts of AN occurred at 328 K (55 °C). An ADN/AN eutectic-phase diagram was constructed from melting-point observations that is useful in studying the effects of AN contamination in ADN decomposition [293]. N_2O evolution was observed at modest temperatures as low as 333 K (60 °C). Some ADN sublimates near its melting point, and then N_2O and AN evolution are very active. At 503 K (130 °C), a small amount of NO_2 was detected in the gas phase, followed by stronger NO_2 evolution at 523 K (150 °C). It was theorized that the ADN decomposition is initiated by proton transfer. Above 503 K (130 °C), dinitraminic acid in the vapor phase decomposes by N–N bond cleavage, evolving NO_2 and initiating a very exothermic reaction sequence.

The sublimation products of ADN contain free dinitraminic acid, which can be trapped in a frozen matrix and identified by IR spectroscopy [294]. Twenty-two absorption bands were identified in the trapped matrix, which were assigned to $\text{HN}(\text{NO}_2)_2$. No evidence was obtained for the presence of structural isomers of hydrogen dinitramide. A suspected but not found isomer was the *aci* form $\text{O}_2\text{N}=\text{NOOH}$, which, according to some molecular orbital calculations, was predicted to be only slightly less stable than the secondary amine structure.

The kinetics of ADN decomposition were studied by a manometric method [241]. The initial decomposition of ADN proceeds via monomolecular cleavage of the N–N bond in the anion. This experiment was supported by the spectrophotometric analysis of the $\text{N}(\text{NO}_2)_2^-$ anion. Gaseous products were analyzed by gas-liquid chromatography (GLC) and mass spectrometry, water was analyzed by the Karl Fisher method, and nitric acid in the products was analyzed by titration with caustic. Thoroughly dried ADN samples with less than 0.2% H_2O showed anomalous decomposition kinetics. At 333 K (60 °C) in the solid state, the decomposition proceeded faster than in the melt at 373 K (100 °C) (abnormal Arrhenius behavior). To avoid the unusual solid-state de-

composition, it is necessary to keep ADN absolutely dry and to control its moisture content.

The autoignition temperature was determined to be 433 K (160 °C) by Wood's metal bath. The thermal stability, measured with microcalorimetry, showed that ADN is stable to at least 353 K (80 °C) and that impurities cause decreased thermal stability. It was also found that ADN in aqueous solution is sensitive to light. Microcalorimetric measurements showed that ADN is thermally stable to 353 K (80 °C), but contaminants will lower the threshold of decomposition. Based on DSC data obtained in accordance with ASTM E698-79, the pre-exponential factor of ADN decomposition is $A_0 = 6.0 \times 10^{15} \text{ s}^{-1}$ and the activation energy is 158 kJ/mol [4].

Slow decomposition of ADN may begin in the solid phase at 333 K (60 °C) to produce gaseous N_2O . ADN begins to decompose rapidly at 403–408 K (130–135 °C), and the DTA/DSC shows an exothermic peak maximum at 453–463 K (180–190 °C) [170]. The thermal decomposition of ADN was studied by DSC and TGA combined with mass spectrometry (TG-MS) and infrared spectroscopy [295]. ADN decomposed in the range 403–503 K (130–230 °C), with an overall heat release of $240 \pm 40 \text{ kJ/mol}$ with pre-exponential coefficients of the order of $A = 10^{21} \text{ s}^{-1}$. The product gases were identified by MS as NH_3 , H_2O , NO , N_2O , NO_2 , HONO , and HNO_3 . The infrared experiments showed that the primary decomposition products are N_2O and NO_2 . No evidence has been found for the participation of dinitraminic acid in the reaction mechanism, and a mechanism involving ionic reactions in the liquid phase was proposed. The global activation energy determined from TGA experiments decreased from $175 \pm 20 \text{ kJ/mol}$ at the beginning of the reaction to $125 \pm 20 \text{ kJ/mol}$ when the reaction neared its completion. Experiments conducted at different carrier gas flow rates indicated that the reaction was catalyzed by product gases released during the reaction. If the product gases are purged fast enough, the decomposition is slowed down. A condensed-phase ionic reaction mechanism was proposed, in which AN and ammonium mononitramide (NH_4NHNO_2) are formed as intermediates in two competing pathways.

Subsequently, temperature-controlled gas cell and thin-film laser pyrolysis techniques have been used to investigate the condensed phase thermal decomposition of ADN [296]. Gas cell experiments were performed at heating rates of $0.02\text{--}0.1 \text{ °C s}^{-1}$ over a temperature range of 293–523 K (20–250 °C). Pulsed CO_2 laser heating of thin ADN films achieved very rapid heating rates of 10^7 °C s^{-1} , and temperatures of about 903 K (630 °C) could be reached in short time. The thermal decomposition products were analyzed in real time by FTIR spectroscopy. Both experimental techniques showed that the primary decomposition products are N_2O and NO_2 . Nitric oxide is produced only at a later stage in the reaction. Surprisingly, no evidence was found for participation of dinitramidic acid in the reaction mechanism. The fact that the same initial products are observed over a wide range of temperatures and heating rates shows that this mechanism can be used to model the initial stages of combustion of ADN.

At 415 K (142°C) in air, ADN will ignite and burn. Other experimenters using a Wood's metal bath for immersing ADN have reported the ignition temperature as 433 K (160°C). Thermogravimetric analysis of ADN decomposition shows that it is a single-stage process. Typical decomposition products are NH_3 , NO , N_2O , H_2O , NO_2 , HONO , and HNO_3 .

The thermal behavior of ADN was characterized by thermomicroscopy, modulated DSC (MDSC), and TGA [167, 297]. The gaseous decomposition products of ADN were captured and analyzed in different heatable optical cells. The decomposition gases were detected in real time on-line during the sample heating by rapid-scan FTIR spectroscopy. All experiments were performed under an argon atmosphere at isothermal conditions or at linear heating rates between 0.5 K min^{-1} and 10 K min^{-1} in the temperature range of 298–548 K (20–275°C). Figure 45, 46, and 47 show three typical DSC thermograms for the decomposition of pure ADN from different sources. There is quite a bit of variation in the onset of exotherm and in the peak temperature. These differences are obviously caused by different purities of the ADN samples used. The sample used by Loebbecke et al. [297] had the lowest melting point and the lowest onset of exotherm and peak exotherm temperature of several data sets published in the literature. The thermograms at a slow heating rate of 0.5 K/min showed the onset of thermal decomposition at 400 K (126.8°C) followed by a symmetrical exothermic peak.

Figure 45: DSC Thermogram of ADN decomposition. (Reprinted and modified from [297], with permission from Elsevier; permission conveyed through RightsLink.)

The exothermic decomposition of ADN proceeded in two steps. The first step resulted in a ~30% mass loss at $T = 433\text{ K} = 160^\circ\text{C}$, and the second step consumed the remaining ~70% of mass at $T = 433\text{--}503\text{ K}$ ($160\text{--}230^\circ\text{C}$). For the reaction $\text{ADN} \rightarrow \text{N}_2\text{O} + \text{AN}$, we would expect a mass loss of 35%. Therefore, the two steps are possibly related to ADN decomposition, first into AN and subsequently to AN decomposition. The two-step thermal decomposition of ADN observed by DSC was confirmed by TGA and high-resolution TGA measurements, showing a mass decrease of 30% in the first step followed by a 70% mass decrease in the second step. There was no residue after completion of the reaction. These results are consistent with a simplified proposed reaction for the first decomposition step of ADN into AN and nitrous oxide with a theoretical mass loss of 35% (Figure 46):

The heat of decomposition was $255 \pm 12.5\text{ kJ/mol}$, and the onset of the exothermic decomposition was at 400 K (127°C). The evaporation curves of NH_4NO_3 and NO_2 pass a maximum, whereas the formation of N_2O is increasing continuously throughout the two steps. See also [298–300].

Figure 47: DSC thermogram of ADN decomposition. (Reprinted and modified from [20] with permission from the American Chemical Society; permission conveyed through RightsLink.)

The thermal decomposition of ADN was measured by TGA, DTA, and MS [301] The DTA/TGA data indicated that the activation energy was 110 kJ/mol in the initial stage and 150 kJ/mol in the terminal stage. Based on analysis of the mass spectra of decomposition products, ADN decomposed to form NO_2 , NH_2OH , and NH_3 above the melting point (365 K = 92°C). This is the only instant where experimenters reported the detection of hydroxylamine free base.

Isotope effects can be observed if the atom that has been substituted by an isotope with a different atomic mass participates in a rate-determining step of decomposition reactions (or any other chemical reactions). The isotope effect is most pronounced when replacing hydrogen ^1H with deuterium ^2H . It is less pronounced when replacing ^{14}N with ^{15}N .

The thermal decomposition of ADN and KDN were examined in the solid state and in solution [166]. Isothermal kinetic rates were measured at 433–493K (160–220°C) by monitoring dinitramide ion disappearance. The reactions were found to be first-order in dinitramide ion. Ammonium ion loss and gas formation were not useful for monitoring ADN decomposition since they reflect the fate of the ADN decomposition product AN. The kinetics of decomposition were nearly identical for ADN neat (proteo- and deuterio-), ADN in water (1 or 20 mass-%), ADN in various pH aqueous buffers, and aqueous KDN (1 mass-% in water or deuterium oxide). The activation energy of ADN decomposition was about 167 kJ/mol (40 kcal/mol) for solid ADN and 155 kJ/mol (37 kcal/mol) for aqueous solutions of ADN. Decomposition of ADN in aqueous buffers proceeded at about the same rate at pH 3, pH 5, and unbuffered, but it decreased by

about 40% at pH 9. Solid KDN was unique in that it decomposed about an order of magnitude slower than ADN, but its decomposition increased to be comparable to that of ADN when KDN was aqueous or when any ammonium salt was mixed in with KDN. Nitrous oxide and nitrate (or nitric acid) were the principal decomposition products of any dinitramide. Nitrogen gas was also formed to a significant extent in the decomposition of ADN and to a small extent in the decomposition of KDN. Isothermal decomposition of ADN in a sealed glass tube showed a tendency to produce more N_2 . For decomposition of neat ADN at $503\text{ K} = 230^\circ\text{C}$, the amount of N_2 was nearly the same as that of N_2O (mol ratio) $N_2/N_2O = 0.6\text{--}0.8$; for ADN in an aqueous solution at $473\text{ K} = 200^\circ\text{C}$, the amounts of N_2 and N_2O were 0.15 and 0.69 mol per ADN mol, respectively. The ^{15}N isotope analysis showed that 90% of N_2 came from a combination of one N atom in ammonium and one N atom in the nitro group, and 90% of N_2O consisted of one N atom in the amine and one N atom in the nitro group. Based on isotope exchange, nitrogen gas resulted from the interaction of ammonium or ammonia with the nitrate or gaseous nitrogen oxides. Studies of ^{15}N -labeled ADN confirmed that one N--NO_2 bond remains intact, forming nitrous oxide, while the other nitro group combines with the nitrogen from ammonium to form nitrogen gas.

The thermal decomposition of dinitramide in aqueous and sulfuric acid solutions was studied over a wide temperature range [253, 302]. Depending on the acidity of the solution, dinitramide is present in three different forms: $\text{N}(\text{NO}_2)^-$ anions, neutral $\text{HN}(\text{NO}_2)_2$ molecules, and protonated $\text{H}_2\text{N}(\text{NO}_2)_2^+$ cations. The rate of the thermal decomposition of dinitramide is dependent on the acidity of the solution. In different experiments, the initial acidity was increased. The sequence in which species decompose is first $\text{N}(\text{NO}_2)^-$ anions, then $\text{HN}(\text{NO}_2)_2$ molecules, and, finally, protonated $\text{H}_2\text{N}(\text{NO}_2)_2^+$ cations. The temperature dependences of the rate constants of the decomposition of $\text{N}(\text{NO}_2)^-$ (k_{anion}) and $\text{HN}(\text{NO}_2)_2$ (k'_{acid}) and the equilibrium constant of dissociation (acidity constant) of $\text{HN}(\text{NO}_2)_2$ (K_a) are as follows:

$$\begin{aligned}k_{\text{anion}} &= 1.7 \times 10^{17} \exp\left(-20.5 \times \frac{10^3}{T}\right), \text{ s}^{-1} \\k'_{\text{acid}} &= 7.9 \times 10^{16} \exp\left(-16.19 \times \frac{10^3}{T}\right), \text{ s}^{-1}, \text{ and} \\K_a &= 1.4 \times 10 \exp\left(-2.6 \times \frac{10^3}{T}\right).\end{aligned}$$

The temperature dependences of the decomposition rate constant of $\text{H}_2\text{N}(\text{NO}_2)_2^+$ ($k_{\text{protonated}}$) and the equilibrium constant of the dissociation of $\text{H}_2\text{N}(\text{NO}_2)_2^+$ ($K_{\text{a-protonated}}$) were estimated as

$$k_{\text{protonated}} = 10^{12} \exp\left(-7.9 \times \frac{10^3}{T}\right), \text{ s}^{-1}$$

and

$$K_{\text{a-protonated}} = 1.1 \exp \left(6.4 \times \frac{10^3}{T} \right).$$

The kinetic and thermodynamic constants obtained make it possible to calculate the decomposition rate of dinitramide solutions in a wide range of temperatures and acidities of the medium. The protonation of the $\text{HN}(\text{NO}_2)_2$ molecules should not affect the strength of the N—N bond, and the orders of the N—N bond in $\text{H}_2\text{N}(\text{NO}_2)_2^+$ and $\text{HN}(\text{NO}_2)_2$ are close. However, when a second proton is added to $\text{HN}(\text{NO}_2)_2$, the protonated form gains the possibility of decomposing via a dehydration reaction. In continuation of these experiments, the decomposition of dinitramide in nitric acid and acetic acid was studied [303]. It was hypothesized that the decomposition in nitric acid occurs via a mixed anhydride N_4O_6 as an intermediate:

Thermal decomposition of ADN and melting points of the ADN/AN binary system and eutectic point were measured by programmed DSC and TGA [168]. The influence of AN on ADN decomposition was studied in detail. When AN was added to ADN, multiple exotherm peaks fused into a single peak at high pressure. The eutectic point is at 30 mass-% AN, with a melting point of 333 K (60 °C). ADN decomposition is retarded by the addition of AN. At high pressures, ADN accelerated the AN decomposition.

A richly illustrated report with 20 DSC and TGA thermograms for several types of ADN samples (prilled, unprilled (Figure 48), and recrystallized) under various experimental conditions (in aluminum and gold-coated aluminum pans; in sealed glass ampoules; under vacuum and pressure) showed asymmetrical or double exothermic peaks with an endothermic peak at a higher temperature [304, 305].

In another test in which the ADN sample was first subjected to an isothermal 325–335 K (52–62 °C) TGA aging process to obtain a residue, followed by the ramp-up DSC, the residue analysis revealed an endothermic peak at 332 K (59 °C) and a lower melting point of 356 K (83 °C) attributed to the presence of AN. It was noted that the first endothermic peak was near the melting point (442.7 K = 169.6 °C) of AN, and the additional exothermic peak was at 310 °C, close to the common AN decomposition temperature of 553–592 K (280–320 °C). Kinetic constants of decomposition were determined for ADN and prilled ADN by DSC and TG. DSC and TG runs in open (pinholed) sample pans in nitrogen or helium had higher activation energies and frequency factors, namely 167–180 kJ/mol (40–43 kcal/mol) and 18–20 min^{−1}, respectively, than in sealed pans. Thus, it appears that confinement of the ADN decomposition gases either under pressurization or a sealed environment accelerates the decomposition of prilled ADN. Kinetics of decomposition of unprilled ADN at atmospheric pressure in

Figure 48: DSC of Bofors ADN under nitrogen at 5 °C/min. (Reprinted and modified from [304], with permission from Elsevier; permission conveyed through RightsLink.)

nitrogen or helium by DSC and TG were $E_a = 154.8 \text{ kJ/mol}$ (37 kcal/mol) and $\log A = 17 \text{ min}^{-1}$. Unprilled ADN had a lower activation energy and frequency factor for decomposition than prilled ADN that contained stabilizers. The effect of sample containment (i.e., aluminum, coated aluminum, gold, and glass ampoules) on the shape of the DSC curve of ADN was investigated. Isothermal TG in vacuum of ADN in the 318–348 K (45–75 °C) region and the DSC analysis of the TG residues showed unusual results in the 333 K (60 °C) region. The rate and enthalpy of decomposition of four other dinitramide salts (ammonium [ADN], hexamethylenetetramine⁺ [HDN], potassium [KDN], and sodium [NaDN]) and their dielectric relaxation were related to the basicity of the cation. The DSC results also suggested that ADN decomposition has a low activation energy in vacuum.

ADN decomposes at 393 K (120 °C). The main pathway is the formation of NH_4NO_3 and N_2O , followed by the thermal decomposition of NH_4NO_3 to N_2O and H_2O at higher temperatures [306, 307]. Gas chromatography/mass spectrometry analysis shows formation of NO_2 , NO , N_2 , and O_2 .

It is known that ADN decomposes at temperatures above its melting point (365 K = 92 °C). The thermal stability of ADN below its melting point had not received much attention until the thermal stability of ADN was studied at temperatures ranging from

328 to 353 K (55 to 80 °C) by using microcalorimetry and TGA at isothermal conditions [308]. The results showed that very dry as-received ADN had a poor thermal stability at 333 K (60 °C), whereas the stability improved at higher temperatures of 343 and 353 K (70 and 80 °C). This anomalous behavior had been observed by other researchers. In more humid samples, the stability at 333 K (60 °C) improves. A possible explanation of the instability of as-received Bofors-ADN at 333 K (60 °C) is that organic impurities, from the 2-propanol used in the last step of the synthesis, may be present. By purification, the ADN becomes substantially more stable at 333 K (60 °C). At higher temperature the organic impurities in as-received ADN volatilize, making the ADN more stable at 343 and 353 K (70 and 80 °C). As-received ADN stored at 353 K (80 °C) showed improved stability when later analyzed at 333 K (60 °C).

For linear pyrolysis under vacuum at 370 K and 0.3–0.5 mbar, an extremely high activation energy of $E_a = 237 \text{ kJ/mol} = 56.7 \text{ kcal/mol}$ with a frequency factor of $1.2 \times 10^{26} \text{ sec}^{-1}$ was obtained using DSC [309]. This is much different from any other reported E_a data for ADN.

Based on differential thermal analysis (DTA) data, the activation energy of ADN decomposition was $E_a = 164 \text{ kJ/mol} = 39.2 \text{ kcal/mol}$, with a frequency factor of $1.52 \times 10^4 \text{ min}^{-1}$ [57]. Based on TGA data, the activation energy calculated from the slope of the Arrhenius curve was 135.7 kJ/mol. The natural logarithm of the pre-exponential factor A was 33.62 [58]. TGA data revealed that E_a changed from 174 to 68.6 kJ/mol (41.6 to 16.4 kcal/mol), while the conversion extent varied from 10 to 90%. The mass loss TGA of ADN at four different temperatures above its melting point is shown in Figure 49. An intermediate step (expected if the decomposition goes to AN first) is barely recognizable from a change in slope after 100 min.

Similar data were obtained for the thermal decomposition of four samples of KDN-ADN mixtures with weight ratios of 90:10, 50:50, 25:75, and 10:90. A thermogram was obtained on a sample of ADN that had been prepared by nitration of ammonium sulfamate [57], shown in Figure 50. The melting points of the samples in Figure 50 and 51 agree quite well, 92.71 °C max and 93.4 °C max.

The thermal decomposition of ADN was studied using TG and DSC for better understanding of the thermal decomposition behavior of ADN [310]. The main variables included the effect of GN_2 purge gas flow rate, ammonium ethyl *N*-nitrocarbamate (AUN, a contaminant from the manufacturing process) content, and AN. Several of these have a strong effect on the ADN decomposition process and influence the activation energy curve of ADN thermal decomposition represented by a model-free isoconversion method. The results showed that the decomposition process of ADN is affected by GN_2 flow rate and AN content but not by AUN content.

In order to study the decomposition mechanisms occurring during the adiabatic self-heating of ADN, a procedure was developed to remove the decomposition gases from the accelerating rate calorimeter system [311]. The main reaction products of ADN were nitrate, nitrogen, and dinitrogen monoxide, which were measured as a function of the degree of ADN conversion.

Figure 50: DSC thermogram of ADN decomposition. (Reprinted and modified from [58] with permission granted by Dr. Santhosh 8-Feb-2021.)

A variety of thermal analysis equipment was used to study the decomposition of ADN crystals and ADN prills by themselves and also in contact with binders, using DSC, TGA, TGA-FTIR-MS, ARC, heat flux calorimetry, and isothermal nanocalorimetry [165, 261]. The average diameters for the crystals and prills were 148 and 154 μm ,

respectively. The prills were coated with 2.4% bis-(2-ethylhexyl)-sebacate (DOS) and 0.6% hydroxyl-terminated polybutadiene (HTPB). In the DSC, two endotherms and two exotherms were obtained for both ADN samples. The first endotherm, which was observed at an onset temperature of about 363 K (90 °C), was due to the melting of ADN, where the melting point may be depressed by impurities. The melting temperature of ADN prills was lower than that of the crystals. The slightly lower melting points of the prills were due to the presence of coating agents. The major exotherm ($\sim 403\text{ K} = \sim 130\text{ °C}$) resulting from the decomposition of liquid ADN was followed by a second exotherm ($\sim 473\text{ K} = \sim 200\text{ °C}$) from the decomposition of AN formed during ADN decomposition. The second endotherm ($\sim 523\text{ K} = \sim 250\text{ °C}$) can be attributed to the formation and vaporization of water during AN decomposition. No second exotherm was observed from the TG-DTA results. With ARC, an exotherm was detected at a true onset temperature of 373 K (100 °C). The onset temperature was 30° lower than that obtained by DSC. This difference was mainly due to the larger sample size used in ARC measurements. All of the ARC runs were stopped automatically at 388–398 K (115–125 °C), when the self-heating rate exceeded 1°/min. The activation energy and pre-exponential coefficient were $E_a = 257 \pm 9\text{ kJ/mol}$ and $\ln Z = 80 \pm 3\text{ min}^{-1}$, which is different from the ARC results reported by SRI ($E_a = 571 \pm 113\text{ kJ/mol}$; $\ln Z = 180 \pm 35\text{ min}^{-1}$).

In one set of experiments, ADN melted at $363.52 \pm 0.49\text{ K}$ ($90.37 \pm 0.49\text{ °C}$), and the onset of exotherm was at $393.80 \pm 0.77\text{ K}$ ($120.65 \pm 0.77\text{ °C}$) [252]. The heat of decomposition was $234.06 \pm 5.55\text{ kJ/mol}$. AN, a frequent contaminant and a decomposition product of ADN, has a pronounced effect on the melting behavior of ADN. A sample contaminated with 3.8% AN showed a new endothermic peak at 331 K (58 °C). AN contamination lowers the thermal stability of ADN, and the AN content should be kept below 0.5%. A very similar DTA thermogram is shown in Figure 51 [7].

In an effort to explain a mechanism for the anomalous decomposition of ADN at 333–338 K (60–65 °C), the ADN decomposition at moderate temperatures was analyzed by a time-of-flight (TOF) mass spectrometer (MS) equipped with a fused silica capillary column inlet. The sample chamber was connected to the ionization chamber of the TOF-MS by a long capillary line [312, 313]. The results from the mass spectrometric studies of decomposition products from solid and molten (100 °C) ADN for two different batches of neat ADN, MgO stabilized neat ADN and prilled ADN showed that stabilization by MgO also retards the formation of N_2O . For the liquid ADN test, the sample was heated to 373 K and kept at that temperature while mass spectra were recorded for several hours. A peak at m/e 45 was attributed to contamination by 2-propanol, which is a solvent used in crystallization of ADN. It disappeared after 3 h. After 21 h at 373 K, the MS showed mostly N_2O with some N_2 and H_2O . There was no signal at m/e 15, and there was no evidence for formation of NH_3 (contrary to what others have reported). After 36 h, water with m/e 18 and 17 was the dominating species in the MS. If 2-propanol can be eliminated as a potential source of the peak at m/e 43, it has been theorized that it could come from hydrogen azide HN_3 , which has not been detected by any previous investigators of ADN decomposition. A sample heated

Figure 51: DSC thermogram of ADN decomposition. (Republished and modified from [7], with permission of John Wiley & Sons Books; permission conveyed through Copyright Clearance Center Inc.)

only to 338 K (65 °C) instead of to 373 K showed some N₂O but no H₂O or NH₃ formed. It was suggested that ADN in the solid state decomposes directly to AN and H₂O:

Under those conditions, the proton transfer mechanism, wherein the first step is a transfer of a proton from the ammonium ion to the dinitramide ion, is not likely to take place. Instead, it has been proposed (as supported by theoretical studies) that the direct formation of N₂O and AN is facilitated by a rearrangement of the dinitramide group, which has a very unsymmetrical electron distribution. The presence of traces of water decreases polarization, smoothens the asymmetry, and thereby prevents an intramolecular rearrangement responsible for the anomalous decomposition. In ADN with 1% MgO added as stabilizer and heated to 368 K, the autocatalytic reaction as measured by heat flow calorimetry was delayed by several days. Prilled ADN (prilled from the melt) contained less (if any) 2-propanol and had a slower onset of decomposition at 373 K than any of the neat (freshly crystallized) ADN samples. The ADN anomalous decomposition is best illustrated by the heat flow calorimeter measurements of samples kept at constant temperatures between 328 and 348 K (55 and 75 °C). Figure 52 shows that the shortest life span is at 338 K (65 °C), with a little longer life span at 333 K (60 °C), but that samples kept at 328, 343, 348, or 353 K (55, 70, 75, or 80 °C) did not decompose measurably within the duration of the experiment (7 d).

Based on the species detected in the mass spectrogram of decomposition products in a dynamic flow reactor, the following equations were proposed to describe the decomposition of ADN (Table 19):

Table 19: Balanced equations for decomposition reactions of ADN.

Equation no.	Balanced equation	Enthalpy of reaction kJ/mol	Entropy of reaction J mol ⁻¹ K ⁻¹	Adiabatic temperature °C
1	$\text{NH}_4\text{N}(\text{NO}_2)_2(\text{S}) \rightarrow \text{O}_2(\text{G}) + 2\text{H}_2\text{O}(\text{G}) + 2\text{N}_2(\text{G})$	-335.7	791	1811

Data source: [314]

The results were compared to those obtained for AN and hydroxylammonium nitrate decomposition. In either case, nitric acid formation competes with oxygen formation. Based on equilibrium calculations using HSC Gibbs, nitric acid is a very stable inter-

mediate kinetic product up to about 523 K (250 °C). Above 573 K (300 °C), HNO_3 decomposes into H_2O and NO_2 .

Samples of ADN prills were prepared by emulsion crystallization and characterized by optical microscopic observation, TGA and DSC [102]. The particle size of ADN prills as measured by optical microscopy was in the range of 100–300 μm . The isothermal and non-isothermal decomposition kinetics were studied using TGA. The differential isoconversional method of Friedman (FR) and integral isoconversional method of Vyazovkin (VY) were used to calculate the dependence of activation energy (E_a) on the degree of conversion (α), and the results were compared to literature data. The dependence of E_a was also derived from isothermal data. A strong dependence of E_a on α was observed for the ADN prills. All the methods showed an initial increase in E_a up to $\alpha \approx 0.2$ and a later decrease over the remaining reaction time, indicating that more than one reaction may be rate determining. However, TGA and DTG showed only one decomposition step. The apparent E_a values of FR method were higher than those of the VY method up to $\alpha \approx 0.45$. The calculated mean E_a values by FR, VY, and standard isoconversional method for α between 0.05 and 0.95 were 211, 204, and 157 kJ/mol, respectively. The TGA measurements showed that ADN prills undergo a single-stage decomposition with a 100% mass loss in the temperature range from 418 to 503 K (145 to 230 °C). The well-defined DTG curve with a peak maximum at $T \approx 454$ K ($T \approx 181$ °C) also indicated that ADN decomposes in a single step. A generalized decomposition mechanism was proposed, based on the assumption that the decomposition of ADN produces various oxides of nitrogen where the formation of ammonia and dinitramidic acid [$\text{HN}(\text{NO}_2)_2$] dominate in the first step (below 373 K = 100 °C), followed by further decomposition of the latter and AN formed by the recombination of NH_3 and HNO_3 at higher temperatures (greater than 373 K = 100 °C).

The rate of thermal decomposition and mechanism of ADN decomposition were investigated using DSC/TGA-MS-FTIR technology [315]. During the thermal decomposition of ADN, N_2O , NO_2 , NH_3 , H_2O , and N_2 were detected and measured in the gas phase by simultaneous TG-DSC-FTIR-MS techniques. The kinetic parameters, activation energy E_a of the evolution of N_2O , NO_2 , and NH_3 gas products were 157, 159, and 100 kJ/mol, respectively. The decomposition mechanism closely resembled a genuine elementary microcosmic process.

Exothermic behavior during thermal decomposition of fresh and aged ADN was measured by isothermal high-sensitivity calorimetry tests and non-isothermal tests using DSC [316]. Figure 53 shows a typical DSC thermogram for fresh ADN. The endothermic peak that was observed at an onset temperature of about 363 K (90 °C) was due to the melting of ADN. Two exothermic peaks are evident at 403–493 K (130–220 °C) (first exothermic peak) and 492–563 K (220–290 °C) (second exothermic peak). The integrated heat value was ~ 1.8 kJ/g for the first exothermic peak and 0.6 kJ/g for the second exothermic peak.

Figure 54 shows heat evolution at different constant temperatures as a function of time. The heat evolution peaked during the first 1–3 d and then subsided.

Figure 54: Heat flow from decomposing fresh ADN during isothermal tests in a microcalorimeter. (Republished and modified from [317], with permission of Springer Nature BV; permission conveyed through Copyright Clearance Center Inc.)

Based on these results, an analysis of the decomposition kinetics was conducted. The activation energy determined by calorimeter tests was lower than that from DSC tests. The value of E_a from calorimeter tests was 80–120 kJ/mol, whereas E_a from DSC tests was 145–165 kJ/mol. That indicated that the decomposition path in calorimeter tests was different from that in DSC tests. The amount of ADN decomposition predicted from calorimeter tests was closer to that found under real storage conditions than the amount of decomposition predicted from DSC tests. Non-isothermal tests may not be able to precisely predict the lifetime of materials with a decomposition mechanism that changes with temperature, such as ADN. The lifetime predicted from DSC results was much longer than that from calorimeter tests, especially at low temperatures. It will be necessary to use isothermal tests to predict the long-term stability at low temperature. Two different samples of ADN were used for the experiments: a fresh sample of ADN-2011 and an aged sample of ADN-1998 (Hosoya Pyro-Engineering) that had been stored in a dedicator for 11 years at room temperature in the dark. The effects of light, heat, moisture, and other factors on the samples vary depending on the area of the sample tested. Therefore, ADN-1998 was separated into a surface-layer sample and a bulk sample from below, which were characterized separately. Based on UV analysis of nitrate ion at 284 nm, the amount of ADN surviving in ADN-1998 was only 36 mass-% ADN at the surface and 57% in the bulk.

ADN was heated at a constant rate, and the exothermic behavior and the decomposition products in the condensed phase during heating were measured simultaneously by Raman spectroscopy, revealing multiple stages of exothermic reactions [317]. In the condensed phase, AN was formed in the primary decomposition at lower temperature, and it further decomposed at higher temperature.

The products and chemical pathways of ADN decomposition reactions under different ambient conditions (pressure, temperature, isothermal or non-isothermal, heating rate, sealed or unsealed) in both the condensed and vapor phases, the thermal stability, and the combustion mechanism were analyzed [318]. It is generally believed that ADN decomposition reaction in the condensed phase will undergo a solid-state molecular rearrangement to form N_2O and AN (or $NH_3 + HNO_3$) at low temperature. However, the decomposition proceeds through N– NO_2 bond cleavage mechanism to form NO_2 at high temperature. For the gas-phase decomposition of ADN, decomposition proceeds mainly via proton transfer in the intramolecular or intermolecular to form dinitraminic acid, $HN(NO_2)_2$, and then dinitraminic acid dissociates following the four pathways:

- $HN(NO_2)_2$ dissociates into NO_2 and $HNNO_2$ radicals, which in turn dissociates to produce various species such as HNO , H_2O , N_2O , and $HONO_2$;
- $O_2NN=N(O)OH$, one of $HN(NO_2)_2$ isomers, decomposes into $NN(O)OH$ and NO_2 radicals;
- $O_2NN=N(O)OH \rightarrow NO_2 + OH + N_2O$; and
- $O_2NN(OH)NO$, another isomer of $HN(NO_2)_2$, which undergoes a four-member molecular rearrangement or possibly proceeds through other transition states, finally dissociates into N_2O and HNO_3 .

4.5.1.2 Effect of Pressure on Thermal Decomposition of Solid Ammonium Dinitramide

Pressure DSC at 3.78 MPa (550 psi) air or helium had similar kinetic constants for prilled ADN, namely 121.3 kJ/mol (29 kcal/mol) activation energy and a log frequency factor of $\sim 14.0 \text{ min}^{-1}$ [304, 305]. These values were similar to those found in sealed sample pans in which the decomposition gases were confined. DSC and TG runs in open sample pans in nitrogen or helium had higher activation energies and frequency factors, namely 167–180 kJ/mol (40–43 kcal/mol) and $18\text{--}20 \text{ min}^{-1}$, respectively. Thus, it appears that confinement of the ADN decomposition gases either under pressurization or a sealed environment accelerates the decomposition of prilled ADN.

For studying the thermal decomposition mechanism of ADN under pressurized conditions from 0.1 to 6 MPa while ADN was heated at a constant rate, the exothermic behavior and the decomposition products in the condensed phase during heating were measured simultaneously using PDSC and Raman spectrometry [319]. PDSC analyses showed multiple stages of exotherms after melting. The exothermic behavior at low temperatures varied with pressure. Analysis of the decomposition products indicated that AN was generated during decomposition of ADN at all pressures. At normal pressure, AN was produced at the same time as start of exotherm. However, the temperature at which the ratio of ADN in chemical species in the condensed phase began to decrease under high pressure was higher than that at atmospheric pressure despite the existence of a significant exotherm.

The main reaction under all pressure conditions was the decomposition of ADN to AN and N_2O . The relative amount of NO_2 decreased with pressure. Condensed phase reactions involving NO_2 take place during early stages of the decomposition process. The reaction mechanism changed in the presence of AN [320].

4.5.1.3 Effect of Moisture on Thermal Decomposition of Solid Ammonium Dinitramide

Moist ADN containing 0.4–0.5% of water was more thermally stable than “dry” ADN containing 0.02–0.05% of water. The kinetics of thermal decomposition of ADN were studied using a manometric method. The thermal decomposition of dinitramide onium salts proceeds via the dissociative mechanism when the $\text{p}K_{\text{a}}$ of the base is lower than 5.0 and via the monomolecular decay of the anion at $\text{p}K_{\text{a}} > 7.0$ [321]. Going from the melt to the solid state, the reaction mechanism of alkali metal dinitramide decomposition does not change, and the rate decreases by 1–2 orders of magnitude. Unusual irregularities are observed for decomposition of ammonium salt and some metal salts in the solid phase: The solid-phase reaction can be $10\text{--}10^4$ times faster than that in the melt. The ADN decomposition rate has a sharp peak at 333 K (60 °C) in the region of eutectics melting with the decomposition product (AN), and it is instantly inhibited by traces of water vapor. In the inhibited regime, the rate in the solid phase is lower than that in the liquid phase. This is related to a change

in the reactivity of the anion due to the violation of its symmetry on going to the solid state. When the nitro groups of the anion are non-equivalent, and the charge is concentrated predominantly on one of them, its reactivity increases, and a new fast pathway of decay is opened: elimination of NO_3^- with elimination of N_2O . Further, the absence of hydrogen bonds between the anion or cations and water molecules is an additional prerequisite for the fast decay [322]. The hydrogen bonds between the anion and H-containing cations in moist samples or direct solvation by water molecules decrease polarization of the anion, smoothen its electronic asymmetry, and prevent intramolecular rearrangement. When water is added to the $\text{NH}_4\text{N}(\text{NO}_2)_2$ melt, the rate of thermal decomposition of the salt first decreases and begins to increase only when the water content is $> 5 \text{ mol-\%}$.

In contrast, no anomalous effects inherent in dinitramide ammonium salt and metal salts in the solid phase were observed during decomposition of onium salts from organic amines [287].

4.5.1.4 Effect of Acids on Thermal Decomposition of Solid Ammonium Dinitramide

It was shown by direct methods that ADN decay can be accelerated by HNO_3 and NO_2 . Both of these both products, as well as water, are highly soluble in molten, liquid ADN. They form during ADN decomposition and cause the process to be self-accelerating. Thermal decomposition of ADN and other dinitramide salts is sensitive to acid catalysis. HNO_3 is one of the decomposition products of ADN, and the addition of HNO_3 aqueous solution to the ADN melt accelerates decomposition [323]. In strong acids, such as H_2SO_4 and HNO_3 , ADN decomposes more rapidly at room temperature, and the rate of acid-catalyzed decomposition is proportional to acidity. Kinetic data for decomposition of different forms of dinitramide and the influence of water on the rate of decomposition of $\text{NH}_4\text{N}(\text{NO}_2)_2$ at 375–412 K (102.4–138.9 °C) show that the contributions of the decomposition of $\text{N}(\text{NO}_2)_2^-$ and $\text{HN}(\text{NO}_2)_2$ to the initial decomposition rate of the reaction at temperatures of about 373 K (100 °C) are approximately equal. The decomposition has an autocatalytic character. The analysis of the effect of additives of HNO_3 solutions and the dependence of the autocatalytic reaction rate constant on the gas volume in the system shows that the self-acceleration is due to an increase in the acidity of the $\text{NH}_4\text{N}(\text{NO}_2)_2$ melt owing to the accumulation of HNO_3 and the corresponding increase in the contribution of the $\text{HN}(\text{NO}_2)_2$ decomposition to the overall rate. At a certain point, the self-acceleration ceases because of the accumulation of NO_3^- ions decreasing the equilibrium concentration of $\text{HN}(\text{NO}_2)_2$ in the melt. The accumulation of HNO_3 in the system is the most probable reason for the self-acceleration of the thermal decomposition during the initial stages of the reaction. The effect of a 26% aqueous solution of HNO_3 (which corresponds to the content of HNO_3 with respect to the sum of HNO_3 and H_2O in the melt at the moment of achievement of the maximum decomposition rate) on the kinetics of thermal decomposition of the $\text{NH}_4\text{N}(\text{NO}_2)_2$ melt was studied by adding known amounts of acid. The acid was introduced in amounts of 3.86 and 1.34 mass-% HNO_3 of the weight of $\text{NH}_4\text{N}(\text{NO}_2)_2$, i.e.,

1.97 and 0.68 mol-% HNO_3 , respectively, with respect to the number of moles of the salt. When pure $\text{NH}_4\text{N}(\text{NO}_2)_2$ decomposes, 0.5 mol-% HNO_3 is present in the system at the moment of achievement of the maximum rate. The increase in the initial rate is proportional to the molar concentration of the added HNO_3 , and its 2.8-fold increase results in a 2.7-fold increase in the rate of decomposition.

NO_2 gas, one of the decomposition products, was found to catalyze ADN decomposition, whereas basic substances, such as NH_3 , amines, and urea, may restrain ADN decomposition.

4.5.1.5 Effect of Contaminants or Additives on Thermal Decomposition of Solid Ammonium Dinitramide

Ammonium nitrate, which is a common contaminant in and decomposition product of ADN, can affect the rate of thermal decomposition of ADN in the solid and molten states [322]. Figure 55 shows the rate of gas evolution (an indicator of ADN decomposition) as a function of time for two ADN samples with different AN content. The sample with the higher AN content (10% AN) evolves gas at a similar rate compared to the sample with only a trace of AN (0.3% AN).

Figure 55: Gas evolution from ADN at $m/V_f = 4 \times 10^{-4} \text{ g/cm}^3$ and temperatures of 150 (curve 1) and 170 °C (curve 2). (Reprinted and modified from [322], with permission by Springer Nature; permission conveyed through Copyright Clearance Center Inc.)

It has been proposed that the effect of higher concentrations of AN in the decomposing ADN is mostly due to the formation of low melting eutectics in the AN/ADN system. This effect is most prominent if the decomposition proceeds at 333 K (60 °C).

The thermal decomposition of ADN and the interaction of ADN with HMX or RDX were investigated by means of DSC and TGA-DTG [324]. The results showed that there existed strong interaction among ADN and HMX or RDX. Because HMX partially dissolved in the molten ADN, the exothermic decomposition peak temperature of ADN increased with the increase of pressure, while that of HMX appeared as a double decomposition peak. A large amount of RDX was liquefied prior to ADN melting, and then it decomposed together with ADN. The decomposition peak temperature of RDX in the mixture at normal pressure would be delayed because of inhibition caused by gaseous products from ADN, while the decomposition peak temperature of RDX at high pressure would be accelerated because of the catalytic effect of gaseous products from RDX decomposition.

4.5.1.6 Effect of Stabilizers on Thermal Decomposition of Solid Ammonium Dinitramide

The thermal stability of ADN is worse than that of AP or AN; therefore, a wide range of stabilizers have been tested in the hope of improving its thermal stability [325].

4.6 Autoignition and Ignition Delay of ADN

The thermal initiation by electron beam heating of single crystals and prills of ADN on a calibrated hot stage has been filmed and recorded in an environmental scanning electron microscope all the way from the formation of microscopic “reaction sites” (0.01 μm in diameter) to full crystal consumption [326]. The transformations of the ADN prills and crystals were compared and recorded in real time at various magnifications (10000 $\times$ to 100 $\times$) and under different atmospheres (pure nitrogen and nitrogen/water vapor mixtures). The initiation characteristics of the prills were found to differ and are related to the microstructural characteristics produced by different prilling techniques, such as the “prilling tower” technique (Thiokol) and the “melt-stir” technique (United Technology Corp. Chemical Systems Division, CSD).

A model with two-phase subsurface reactions was developed to study the physical and chemical processes involved in ADN autoignition [327]. The model was based on the conservation equations of mass, species concentration, and energy for both the condensed phase and the gas phase, and it takes into account finite-rate chemical kinetics and real thermophysical properties. A kinetics scheme containing 35 species, two global ADN decomposition reactions in the condensed phase, and 166 reactions in the gas phase was used to describe the process. The ignition model was applied to predict ADN autoignition delay time (induction period) at various initial temperatures at 0.1 MPa. The agreement between calculation predictions and experimental results

was satisfying, which indicated that the model can predict the ADN ignition process accurately. The results showed that ADN ignition delay time decreased rapidly with an increase of initial temperature. An extension of this model was used to model the linear burning rate of ADN once it has ignited.

4.6.1 Fitting ADN Thermal Decomposition Rate Data to Kinetic Models

Comparative decomposition studies on KDN and HDN are helpful in investigating the key chemical processes involved with ADN decomposition. A widely used model-fitting method gave excellent fits to the experimental data for the thermal decomposition of ADN (ADN), but yielded highly uncertain values of the Arrhenius parameters when applied to non-isothermal data because temperature and extent of conversion are not independent variables [328]. Therefore, a comparison of model-fitting results from isothermal and non-isothermal experiments is practically meaningless. On the other hand, model-free isoconversional methods of kinetic analysis yield similar dependencies of the activation energy on the extent of conversion for isothermal and non-isothermal experiments. Analysis of synthetic data generated for a complex kinetic model suggests that, in the general case, the identical dependencies are unlikely to result from experiments obtained under isothermal and non-isothermal conditions.

The model-free and model-fitting kinetic approaches were applied to data for non-isothermal and isothermal thermal decompositions of HMX and ADN [329]. The popular model-fitting approach gave excellent fits for both isothermal and non-isothermal data but yielded highly uncertain values of the Arrhenius parameters when applied to non-isothermal data. These values could not be used to reasonably predict the isothermal kinetics, but the dependence derived from non-isothermal data enabled reliable predictions of the isothermal kinetics.

One of the intermediates in ADN decomposition in the gas phase may be nitroamine, which was already discussed as a potential intermediate in the production of ADN. The decomposition of nitroamine can be modeled using the same set of kinetic parameters as those that will be needed for modeling ADN decomposition [46].

4.6.2 Modeling the Thermal Decomposition Reactions of Solid Ammonium Dinitramide from Scratch (ab initio)

The initial step in the thermal decomposition of ADN was the subject of vigorous discussions during the decade following its discovery. The first decomposition step could be as follows:

- (a) conversion to AN and NO_2
- (b) sublimation to NH_3 and $\text{HN}(\text{NO}_2)_2$
- (c) dissociation of the dinitramide ion $\text{N}(\text{NO}_2)_2^-$ through the loss of either NO_2 or NO_2^-
- (d) conversion of the dinitramide ion to N_2O and NO

It is, of course, quite possible that two or more of these processes are occurring simultaneously. These initial steps are followed by some series of subsequent reactions, leading eventually to products that may include combinations of HNO_3 , N_2O , NO_2 , NH_3 , H_2O , NO , HNO_2 , N_2 , and more. Figure 56 illustrates the multitude of decomposition pathways and subsequent reactions in the decomposition of solid ADN.

Figure 56: Possible pathways and subsequent reactions in the decomposition of solid ADN (Adapted from Politzer, Seminario, and Concha [330].)

In addition to using computational chemistry to model the thermal decomposition of ADN and other energetic materials, the same methods can also be used to model the actual combustion of ADN either by itself or in combination with a combustible fuel (Section 4.11.2.2).

With the advances of computational chemistry came the ability to calculate and predict not only the thermodynamic properties of energetic materials but also the paths taken by thermal decomposition reactions. Nitramide H_2NNO_2 , closely related to dinitramide, is an intermediate in the production and decomposition of ADN and its decomposition into amino radicals and nitrogen dioxide or water and nitrous oxide, and rearrangement has been modeled based on quantum chemical calculations (also for dimethylnitramide) [331].

Aside from the exothermic decomposition of hydrogen dinitramide (dinitramidic acid) to N_2O and HNO_3 , the gas-phase oxidation of NH_3 by NO_2 seems to be responsible for the exothermicity of the ADN decomposition. The kinetics and mechanisms of the $\text{NH}_3 + \text{NO}_x$ ($x = 1, 2$) reactions have been systematically studied by pulsed laser photolysis/mass spectrometry (PLP/MS) and pyrolysis/FTIR spectrometry (P/FTIRS) [332]. In the PLP/MS experiment, the total rate constants and product-branching ratios of the $\text{NH}_2 + \text{NO}_x$ ($x = 1, 2$) reactions were tested by measuring the time-resolved

concentrations of H_2O , N_2O , and NO_2 in the laser-initiated reaction of NH_3 with NO in the presence of varying amounts of NO_2 in the temperature range of 300–725 K. Agreement between the kinetically modeled and experimentally measured concentrations was quite satisfactory for the reactants and products. A remote hope is that once the $\text{NH}_3 + \text{NO}_x$ reactions are better understood, they might be tuned (high pressure?) and aimed at the synthesis of ADN in reversal of the decomposition reaction.

The structures, energetics, and decomposition mechanisms of gaseous ADN and ammonium nitrite (NH_4NO_2) have been studied theoretically by different *ab initio* molecular orbital (MO) approaches [333]. Ammonium nitrite, an unstable compound, was chosen because it has some structural similarity with ADN. In the gas phase, both species have the structures not of ionized salts but rather of molecular complexes $[\text{NH}_3] \bullet [\text{HX}]$, which are stable after vaporization. For NH_4NO_2 , $[\text{NH}_3] \bullet [\textit{trans}\text{-HONO}]$ is the most stable isomer. The $[\text{NH}_3] \bullet [\textit{cis}\text{-HONO}]$ and $[\text{NH}_3] \bullet [\text{HNO}_2]$ structures lie higher by 5.8 and 35 kJ/mol (1.4 and 8.4 kcal/mol). For the gaseous ADN, $[\text{NH}_3] \bullet [\text{HN}(\text{NO}_2)_2]$ is the most stable structure, while the $[\text{NH}_3] \bullet [\text{HON}(\text{O})\text{NNO}_2]$ isomer is 9.6 kJ/mol (2.3 kcal/mol) less favorable. The calculated dissociation energies of the $[\text{NH}_3] \bullet [\text{HX}]$ complex to NH_3 and HX are 33.5–37.7 and 50.2–58.6 kJ/mol (8–9 and 12–14 kcal/mol) for NH_4NO_2 and ADN, respectively. The energies for elimination of the NO_2 group from $\text{HN}(\text{NO}_2)_2$ and $\text{HON}(\text{O})\text{NNO}_2$ are found to be 159–167 kJ/mol (38–40 kcal/mol), while the barrier for $\text{HON}(\text{O})\text{NNO}_2$ dissociation is about 176 kJ/mol (42 kcal/mol). The following values of the heats of formation, $\Delta H_f^0(0)$, in the gas phase were predicted as follows: –148.5 kJ/mol (–35.5 kcal/mol) for $[\text{NH}_3] \bullet [\textit{trans}\text{-HONO}]$, +104 kJ/mol (+24.9 kcal/mol) for $\text{HN}(\text{NO}_2)_2$ and +13.4 kJ/mol (+3.2 kcal/mol) for $[\text{NH}_3] \bullet [\text{HN}(\text{NO}_2)_2]$. Based on these *ab initio* MO calculations, a realistic mechanism for the decomposition of ADN was proposed, which is fully consistent with the decomposition products measured by Brill, Brush, and Patil [334]. It was concluded that $[\text{NH}_4]^+ [\text{N}(\text{NO}_2)_2]^-$ is not a local energy minimum, and the ionic structure of ADN does not exist in the gas phase. Dinitramidic acid can exist in two isomeric forms:

Accordingly, the energy levels of two different isomers of the ADN molecular complex were calculated, and the most favorable structure and two less favorable structures were drawn in 3D. $[\text{NH}_3] \bullet [\text{HN}(\text{NO}_2)_2]$ is the most stable structure in the gas phase at all the levels of calculation, while $[\text{NH}_3] \bullet [\text{HON}(\text{O})\text{NNO}_2]$ and the unstable $[\text{NH}_4]^+ [\text{N}(\text{NO}_2)_2]^-$ ionic structure lie higher by 9.6 and 50.6 kJ/mol (2.3 and 12.1 kcal/mol), respectively. The heat of formation of ADN in the gas phase was calculated to be +13.9 kJ/mol (+3.2 kcal/mol). In order to estimate $\Delta H_f^0(0)$ for ADN in the solid phase, one has to add the sublimation energy to this value. The theoretical research by Michels and Montgomery [209] and Politzer et al. [335] largely supported the case for dissociation of $\text{HON}(\text{O})\text{NNO}_2$ into N_2O and HNO_3 , while the results of Mebel et al. [333] tend to support the N– NO_2 bond cleavage of $\text{HN}(\text{NO}_2)_2$ forming NO_2

with no acid catalysis. All calculations predict that the ion-pair $[\text{NH}_4]^+[\text{N}(\text{NO}_2)_2]^-$ is not stable in the gas phase. A more stable configuration is the H-bonded acid-base pair $[\text{NH}_3][\text{HN}(\text{NO}_2)_2]$ similar to the isomeric $[\text{NH}_3] \bullet [\text{HON}(\text{O})\text{NNO}_2]$, which is only 9.6 kJ/mol (2.3 kcal/mol) less stable.

Proton transfer in gaseous ADN clusters up to $(\text{ADN})_2$ was studied using DFT [336]. A similar study had been conducted a year earlier on AN clusters [337]. Proton transfer between the hydrogen dinitramide and ammonia units does not occur in the ADN monomer. Instead, the ammonia-hydrogen dinitramide complex is stabilized by strong hydrogen bonding. However, proton transfer between hydrogen dinitramide and ammonia is predicted in the following three clusters: ADN dimer $[\text{NH}_3\text{HN}(\text{NO}_2)_2]_2$, ADN solvated with a single ammonia molecule $\text{NH}_3 \bullet [\text{NH}_3\text{HN}(\text{NO}_2)_2]$, and ADN solvated with a hydrogen dinitramide molecule $[\text{NH}_3\text{HN}(\text{NO}_2)_2]_2 \bullet [\text{HN}(\text{NO}_2)_2]$. The binding energies of the clusters and total electrostatic interaction energy in each cluster were calculated using population analysis. The electrostatic energy is a measure that distinguishes between the ionic or hydrogen-bonded nature of the clusters. Proton transfer in ADN clusters can have a significant influence on the decomposition mechanism of ADN and its parent acid, HDN, as shown in a subsequent paper by the same authors:

According to those calculations [338], gas-phase dinitramidic acid (HDN) decomposes along two pathways, one involving a molecular rearrangement,

and a second initiated by N—N bond fission,

A molecular rearrangement pathway for the gas phase dinitramide ion,

can also occur. The reaction rates and pathways for the decomposition of HDN and the corresponding dinitramide ion were calculated using DFT calculations. The energy levels of the geometries, vibrational frequencies, and zero-point energies of the reactants, products, and transition states involved in the gas-phase decomposition of $\text{HN}(\text{NO}_2)_2$ were calculated. The lowest energy pathway for N_2O formation initially involves an internal proton transfer in the HDN molecule. The system then passes through a four-center transition state that has a protonated bridge oxygen atom. The energy of this geometry is 147.3 kJ/mol (35.2 kcal/mol) higher than the reactant from which it is formed. This path had not been previously identified. The rates of N_2O elimination were calculated, and the rates of HDN and $\text{N}(\text{NO}_2)_2^-$ decomposition were compared with each other and with the rate of N—N bond fission in dinitraminic acid. The reaction

could not proceed by a simple bond cleavage. It needs to undergo a four-member molecular rearrangement ($\text{O}_2\{\text{NONN}\}\text{O}$) or proceed through other transition states.

Non-local DFT is an effective means for determining the energetics and mechanisms of decomposition processes of energetic materials such as ADN, nitramine, and substituted nitramines of real chemical interest and practical significance [335, 339]. It can be viewed as a tool that is available as a useful supplement to existing experimental techniques but with the additional advantage that it can be applied to hypothetical, envisioned molecules that may not yet have been synthesized. A non-local density functional procedure (DF/GGA/DZVPP) was used to compute the structure of the dinitramide anion $\text{N}(\text{NO}_2)_2^-$ and the energetics of some possible decomposition paths. The NO_2 groups can be rotated out of the N—N—N plane, with a considerable difference between the two N—N—O angles of each NO_2 group. Of three possible N—N bond-breaking reactions, the least energy is required to yield NNO_2^- and NO_2 ($208 \text{ kJ/mol} = 49.8 \text{ kcal/mol}$). It is possible that NNO_2^- and NO_2 form a loosely knit complex. Nitramine $\text{H}_2\text{N}-\text{NO}_2$ is an intermediate in the formation as well as the decomposition of ADN. Gaussian-2 (G2) and non-local DFT (DFT-GGA) were used to calculate the energy requirements for (1) $\text{H}_2\text{N}-\text{NO}_2$ dissociation (through N—N bond scission), (2) inversion of the amine group, and (3) isomerization through the nitro–nitrite rearrangement [340].

The structures, zero-point energies at 0 K, and enthalpies at 298 K of 37 gaseous molecules, fragments, free radicals, ions, and transition states that have been implicated as intermediates and products in the thermal decomposition of ADN have been computed using a density functional procedure DF/B3P86/6-31 + G** [330]. $\Delta H(0 \rightarrow 298)$ is the enthalpy change in going from 0 to 298 K; it includes the zero-point contribution. These data permit the calculation of ΔH_{298} for a large number of possible decomposition steps. The lattice enthalpy of ADN is $\Delta H_{298} = 602 \text{ kJ/mol} = 144 \text{ kcal/mol}$. This seems quite reasonable when compared to literature values for other ammonium salts, e.g., NH_4NO_3 , 163 kcal/mol , and NH_4ClO_4 , 140 kcal/mol . The heat of sublimation of ADN with proton transfer to molecular $\text{NH}_3^+\text{HN}(\text{NO}_2)_2$ is $\Delta H_{298} = 184 \text{ kJ/mol} = 44 \text{ kcal/mol}$, and the gas-phase heat of formation of $\text{HN}(\text{NO}_2)_2$ is $\Delta H_{298}^f = 79.5 \text{ kJ/mol} = 19 \text{ kcal/mol}$. The decomposition rate of $\text{HN}(\text{NO}_2)_2$ is 10^7 – 10^8 times higher than that of $\text{N}(\text{NO}_2)_2^-$ for $t = 273$ – 373 K (0 – 100°C) since the anion $\text{N}(\text{NO}_2)_2^-$ has a higher activation energy than $\text{HN}(\text{NO}_2)_2$. Further, the protonated $\text{H}_2\text{N}(\text{NO}_2)_2^+$ has a more rapid decomposition rate than $\text{HN}(\text{NO}_2)_2$. The poor stability of $\text{HN}(\text{NO}_2)_2$ may be attributed to a weaker N—N bond in $\text{HN}(\text{NO}_2)_2$ as compared with $\text{N}(\text{NO}_2)_2^-$. The N—N bond in $\text{N}(\text{NO}_2)_2^-$ has a bond order between the double ($\text{N}=\text{N}$) and single ($\text{N}-\text{N}$) bonds, whereas N—N in $\text{HN}(\text{NO}_2)_2$ and in protonated $\text{HN}(\text{NO}_2)_2^+$ has a bond order closer to a single N—N bond.

Molecular dynamics simulations are useful for predicting the thermal stability of energetic compounds as well as their sensitivity toward other stimuli [341]. This can provide a better understanding of how factors related to the crystal lattice, e.g., defects, influence the initiation and propagation of detonation.

Earlier experiments revealed two important channels of ADN decomposition: The first one is associated with the formation of AN in the melted ADN layer, and the second one is based on ADN sublimation (evaporation) at low pressures. In order to clarify the kinetic mechanism proposed previously for the description of the structure and reactant concentration profiles of ADN flames, the chemical processes in thermal decomposition products and ADN flame with a pressure of 10 mm Hg and 3–40 atm were modeled numerically [342]. Results of numerical simulation of pyrolysis of undissociated ADN sublimation products in a flow reactor in a temperature range of 373–920 K for a pressure of 10 mm Hg were compared with a numerical simulation of NH_3 reaction with $\text{HN}(\text{NO}_2)_2$ under conditions of high temperatures and low pressures. The reasons for significant differences in results calculated with the use of one-dimensional models were not quite understood. Adaptation of one-dimensional numerical algorithms to fast processes and qualitative estimation of the contribution of the heating zone to chemical processes may lead to a better understanding of the decomposition process. Based on a comparison of numerical and experimental data, the contributions of individual stages and components to the pyrolysis process and the values of rate constants were estimated. It was concluded that the ADN sublimation process follows the dissociative mechanism

followed by reaction of NH_3 with $\text{HN}(\text{NO}_2)_2$ in the gas phase. The Ermolin 2004 paper [342] contains a long list of 218 (!) individual, fundamental reactions that may contribute to the $\text{HN}(\text{NO}_2)_2/\text{NH}_3$ reactions, complete with pre-exponential factor, activation energy, and literature source. This very complete list is also useful for any other kinetic studies involving only oxygen, nitrogen, and hydrogen in the absence of any carbon species.

In order to get a more detailed molecular insight and to correlate the experimental data with bond-dissociation processes, quantum mechanical calculations were performed with the DMol³ program from Biovia (previously named Accelrys) to get bond-dissociation energies and bond-dissociation enthalpies for possible involved bonds in ADN [343].

The mechanism for sublimation of ADN has been investigated quantum-mechanically with generalized gradient approximation plane-wave DFT calculations [197]. The solid surface was represented by a slab model, and periodic boundary conditions were applied. The calculated lattice constants for the bulk ADN, which were found to consist of $\text{NH}_4^+[\text{ON}(\text{O})\text{NNO}_2]^-$ units instead of $\text{NH}_4^+[\text{N}(\text{NO}_2)_2]^-$, agreed quite well with experimental values. Results showed that three steps were involved in the sublimation/decomposition of ADN. The first step was the relaxation of the surface layer with 6.7 kJ/mol (1.6 kcal/mol) energy per $\text{NH}_4\text{ON}(\text{O})\text{NNO}_2$ unit, and the second step was the sublimation of the surface layer to form a molecular $[\text{NH}_3]^+[\text{HON}(\text{O})\text{NNO}_2]^-$ complex with a 123 kJ/mol (29.4 kcal/mol) sublimation energy, consistent with the experimental observation of Korobeinichev et al. The last step was the dissociation of

the $[\text{NH}_3]^- [\text{HON}(\text{O})\text{NNO}_2]$ complex to give NH_3 and $\text{HON}(\text{O})\text{NNO}_2$ with a dissociation energy of 58 kJ/mol (13.9 kcal/mol). Direct formation of $\text{NO}_2(\text{G})$ from solid ADN would require a higher energy, 244 kJ/mol (58.3 kcal/mol). The calculated total sublimation enthalpy for

188 kJ/mol (44.9 kcal/mol) via three steps, was in good agreement with the value of 176 kJ/mol (42.1 kcal/mol) predicted for the one-step sublimation process in this work and the value of 184 kJ/mol (44.0 kcal/mol) computed by Politzer et al. using experimental thermochemical data. The sublimation rate constant for the rate-controlling step 2 could be represented as

$$k_2 = 2.18 \times 10^{12} \exp\left(-30.5 \frac{\text{kcal/mol}}{RT}\right) \text{s}^{-1},$$

which agreed well with available experimental data within the temperature range studied. For other quantum mechanical and *ab initio* treatments of ADN decomposition, see also [230, 344].

Ionization and decomposition pathways of ionized ADN have been analyzed using DFT methods, coupled cluster theory, and the composite complete basis set CBS-QB3 method [345]. The $\text{NH}_4\text{N}(\text{NO}_2)_2^+$ ion dissociates into the stable dinitramide radical and NH_4^+ with a dissociation enthalpy of 50 kJ/mol. The subsequently formed $\text{N}^+(\text{NO}_2)_2$ ion has an activation enthalpy of 102 kJ/mol for decomposition into N_2O , O_2 , and NO^+ . A competing pathway for ionization and decomposition of ADN involves the $\text{HN}^+(\text{NO}_2)_2$ ion, which dissociates into NO_2^+ and HNNNO_2 with a barrier of only 17 kJ/mol. The ionization product HN^+NO_2 is stable toward further decomposition, and the barrier for isomerization to HONNO^+ is 167 kJ/mol. The computed adiabatic ionization potentials of ADN, $\text{HN}(\text{NO}_2)_2$, $\text{N}^-(\text{NO}_2)_2$, and HNNNO_2 are 9.4, 11.5, 10.2, and 10.9 eV, respectively.

The effect of solvents on the decomposition of ADN was analyzed theoretically, including a path for decomposition of different proton transfer isomers via dinitramidic acid (HDN), $(\text{HDN})_2$, and $(\text{ADN})_2$ clusters and the effects of an intramolecular and intermolecular double proton transfer process on the decomposition reactions of different isomers [346]. The effect of trace water in $(\text{H}_2\text{O})_n \cdot \text{NH}_4^+ [\text{N}(\text{NO}_2)_2]^-$ ($n = 1, 2, 3$) and $(\text{ADN})_2$ clusters on the abnormal decomposition behavior of ADN was discussed. The kinetic parameters obtained in the larger $(\text{ADN})_n$ clusters agreed with some experimental results. The study showed that the introduction of the QM-MM method, which was suitable for the larger $(\text{ADN})_n$ clusters and solvation model in the liquid phase and gas phase, enabled prediction of relevant thermodynamic and kinetic parameters of ADN decomposition.

A detailed chemical kinetics model for the liquid-phase reactions of ADN based on quantum chemical calculations was used to calculate the thermal corrections, entropies, and heat capacities of chemical species from the partition function using sta-

tistical thermodynamic methods [347]. Rate coefficients were determined to allow the application of transition state theory and variational transition state theory to reactions identified in previous studies. The new model simulated the thermal decomposition of ADN under specific heating conditions and successfully predicted heats of reaction and the gases that resulted from decomposition under those conditions. The thermal behavior predicted from this model was an excellent match with the experimental behavior observed from thermal analysis using DSC and Raman spectroscopy.

Results from an overall decomposition mechanism computation of ADN in the gas phase via DFT calculations were compared with experimental TGA-FTIR and TGA-MS results [348]. In the thermal decomposition of gaseous ADN [ADN(G)], ADN(G) first decomposed into dinitraminic acid $[\text{HN}(\text{NO}_2)_2]$ and NH_3 , followed by $[\text{HN}(\text{NO}_2)_2]$ decomposition into other products with smaller molecules. $[\text{HN}(\text{NO}_2)_2]$ was found to isomerize into five isomers in the gas phase. For the initial decomposition of $[\text{HN}(\text{NO}_2)_2]$, the favorable decomposition pathway via a structure of $\text{HON}(\text{O})\text{NNO}_2$ was more likely to form HNO_3 and N_2O with a large release of energy (approximately 188 kJ/mol [45 kcal/mol]). HNO_3 and NH_3 can first combine to form NH_4NO_3 , which is relatively stable but will decompose in subsequent steps. Both calculated and experimental results indicated that the product N_2O is first formed in the thermal decomposition of ADN(G). Other products are NH_3 , H_2O , NO , NO_2 , HONO , and HNO_3 .

4.7 Thermal Decomposition of Vapor-Phase Ammonium Dinitramide

Because ADN may sublime and exist in the vapor phase in the form of molecular additives, the discussion of experimental studies of the decomposition process in this book has been separated into condensed-phase decomposition studies and vapor-phase decomposition studies. This is in addition to the computational chemistry studies summarized in the previous section. Reactions of decomposition products of ADN in the gas phase are very similar to NO_x/NH_3 reactions such as those that take place in the DeNO_x process for stack gas decontamination to reduce air pollution from power plants. There are numerous publications on this subject, but they are not included in our review of the ADN decomposition reactions in the gas phase. The same reactions also limit the yield of dinitramide during the reaction of dinitrogen pentoxide or other nitryl salts with ammonia during ADN production.

Mass spectrometric analysis of ADN decomposition products at low pressure showed the appearance of the NH_3 peak much earlier than decomposition experiments at atmospheric pressure [349]. ADN pyrolysis is dominated by decomposition into NH_3 and $\text{HN}(\text{NO}_2)_2$ (hydrogen dinitramide, HDN) in analogy to NH_4NO_3 , with a maximum rate of decomposition under these conditions at approximately 428 K (155 °C). The two vapor-phase components regenerated ADN on cold cryostat surfaces in addition to deposition of the pure acid HDN and H_2O . Condensed phase HDN was found to be stable for indefinite periods of time at ambient temperature and

vacuum conditions, whereas fast heterogeneous decomposition of HDN at higher temperature led to N_2O and HNO_3 . The HNO_3 then underwent fast (heterogeneous) decomposition. Gas-phase HDN also underwent fast heterogeneous decomposition to NO and other products, probably on the internal surface (about 333 K [60 °C]) of the vacuum chamber before mass spectrometric detection. Other nitramines studied under similar conditions and compared to ADN decomposition products were NH_4NO_3 , NH_2NO_2 , RDX, and $\text{AgN}(\text{NO}_2)\text{CH}_2\text{CN}$ [350].

The thermal decomposition of ADN in the gas phase has been studied at 373–920 K by pyrolysis/mass spectrometry under low-pressure (10-mm-Hg) conditions [351]. The reaction of the sublimed mixture of NH_3 and $\text{HN}(\text{NO}_2)_2$ (hydrogen dinitramide, dinitraminic acid) was found to be initiated by the unimolecular decomposition of dinitraminic acid,

followed by the rapid decomposition reaction

The measured absolute yields of NH_3 , H_2O , N_2 , and N_2O could be satisfactorily modeled by employing the theoretically computed values of

$$k_2 = 6.79 \times 10^{48} T^{-11.0} \exp(-21780/T) \text{ s}^{-1}$$

and

$$k_3 = 7.53 \times 10^{24} T^{-2.9} \exp(-12958/T) \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

by high-level *ab initio* molecular orbital and canonical variational calculations. It was concluded that ADN is unstable in its ionic form, $\text{NH}_4^+\text{N}(\text{NO}_2)_2^-$, and its sublimation leads to the formation of two molecular complexes, $\text{H}_3\text{N} \bullet \text{HN}(\text{NO}_2)_2$ and $\text{H}_3\text{N} \bullet \text{HON}(\text{O})\text{NNO}_2$, which are more stable than the dissociated states, $\text{NH}_3 + \text{HN}(\text{NO}_2)_2$ and $\text{NH}_3 + \text{HON}(\text{O})\text{NNO}_2$, by 51.9 and 59.0 kJ/mol (12.4 and 14.1 kcal/mol), respectively. The yields of N_2 , N_2O , H_2O , and NH_3 measured in the thermal decomposition of ADN could be satisfactorily accounted for with a mechanism consisting of 152 reactions, assuming that initial concentrations of NH_3 are approximately equal to that of $\text{HN}(\text{NO}_2)_2$.

In another study [352] of ADN thermal decomposition by TOF-MS at pressures of about 0.000001 Hg, 100 mm Hg, and 1 atmosphere within a temperature range of 373–573 K (100–300 °C) at isothermic and non-isothermic conditions, the rate of reaction was expressed as

$$W = \frac{d\alpha}{dt} = 3.5 \times 10^{15} [\exp(-32000/RT)](1 - \alpha) \text{ s}^{-1}.$$

Peaks were observed at $m/e = 17$ (NH_3^+ , OH^+), 18 (H_2O^+), 28 (N_2^+), 30 (NO^+), 46 (NO_2^+), and 63 (HNO_3^+). The data indicated that mass spectra of ADN decomposition

products at 1 atm or 100 mm Hg differ significantly from mass spectra of ADN decomposition products in vacuum, especially at the m/e ratio 146/117, which is 1.5–1.7 in the first case, while in vacuum it is in the range of 0.06–0.16. For comparison, thermal decomposition of AN was measured in the same apparatus at 10^{-6} mm Hg. In this case, the reaction products were ammonia and nitric acid. The rate of ADN decomposition increased with decreasing pressure, and the HNO_3 mol fraction in the decomposition products decreased. One reason is that the process of ADN dissociative sublimation into NH_3 and HDN followed by decomposition of the latter to give N_2O , NO , and H_2O becomes dominant with decreasing pressure. During a test at 10^{-3} atm, 90% of the ADN sublimed and deposited on the cold wall of the tube. See also [353–355]. Temperature profiles through the flame front of burning ADN/HTPB propellant with 3% binder indicated that the dark zone contains ADN decomposition products [356, 357].

The thermal decomposition of ADN in the gas phase has been studied at 373–920 K by pyrolysis/mass spectrometry under low-pressure conditions using a Saalfeld reactor [344, 358]. The reaction of the sublimed mixture of NH_3 and $\text{HN}(\text{NO}_2)_2$ was found to be initiated by the unimolecular decomposition of dinitraminic acid:

followed by the rapid decomposition reaction

The measured absolute yields of NH_3 , H_2O , N_2 , and N_2O , calibrated with standard mixtures, at 10 mm Hg He carrier gas pressure could be quantitatively modeled by employing the theoretically calculated values of

$$K_2 = 5.0 \times 10^{15} \exp(-17620/T) \text{ s}^{-1}$$

and

$$K_3 = 7.53 \times 10^{24} T^{-2.9} \exp(-16600/T) \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}.$$

A mechanism involving 152 reactions with recommended rate constants is presented that can be programmed into a program such as CHEMKIN.

The vapor pressure at temperatures of 353–413 K (80–140 °C), the heat of vaporization, and the thermal decomposition of ADN were studied using a two-temperature flow reactor [359]. ADN vapors were formed in the first stage of a flow reactor at 353–413 K (80–140 °C) and ducted into the second stage, where they would either condense or decompose, depending on the temperature in the second stage. Based on these results, a mechanism for the thermal decomposition of ADN was proposed that included the ADN vaporization stage, i.e., the transition from the condensed to the gaseous state in the form of a molecular complex $\text{NH}_3 \cdot \text{HN}(\text{NO}_2)_2$, followed by dissociation into NH_3 and $\text{HN}(\text{NO}_2)_2$. The composition of the products from the thermal decomposition of ADN vapor at temperatures of 433–1173 K (160–900 °C) was determined by molec-

ular beam mass spectrometry, but no HNO_3 was observed at $m/e = 63$. The effective rate constant for the dissociation of ADN vapor was determined by repeating the experiments at different temperatures from 433 to 593 K (160 to 320 °C). After completion of the experiments, the overall thermal decomposition of ADN vapor in a flow reactor was modeled theoretically using the proposed mechanism and the reaction rate constant for ADN vapor dissociation, and the agreement between experimental and theoretical results was satisfactory. See also [360].

4.8 Rapid Heating Thermal Decomposition and Flash Pyrolysis of ADN with Analysis of Intermediate Products

The mechanisms of ADN decomposition can be identified by analyzing the off-gassing during rapid thermolysis (pyrolysis) of ADN crystals. Depending on the rate of heat application, the surface of the crystals may decompose before it has a chance to melt. The methods for analysis must have a short response time such that a time-resolved sequence of the various intermediate species and reaction products as well as their momentary concentrations can be obtained. The rapid-response methods of analysis used most often are FTIR (T-Jump FTIR) and TOF-MS. The methods of rapid heating consist of either placing a thin film of the sample on a resistance-heated platinum ribbon or zapping the sample with a laser.

4.8.1 Mass Spectrometric Analysis of Intermediate Products During Rapid Decomposition

Mass spectrometry is useful for analyzing ADN decomposition products during slow, low-temperature decomposition as well as during rapid, high-temperature decomposition. There are several methods to flash-pyrolyze ADN and other energetic materials in order to analyze the decomposition products by MS or other fast-analysis methods. The resistance-heated hot metal foil method has been described elsewhere. Another fast method is laser flash pyrolysis, in which the amount and the intensity of energy delivered to the surface can be accurately dosed.

The results of CO_2 laser-induced deflagration of ADN were presented as a function of pressure (0.1–3.0 atm of argon) and incident laser heat flux (20–300 W/cm^2) [361]. Spatial and temporal profiles of gaseous species concentrations were obtained by microprobe sampling and MS analysis. Both gas-phase temperature profiles and surface temperatures were measured with fine-wire thermocouples. Visual observations of the laser heating event recorded with a high-magnification fast video recording system allowed a direct view of the process and revealed a surface melt layer with tiny gas bubbles that was evident at pressures of 1 atm or lower. A luminous flame was observed only when the pressure was raised to greater than 3 atm, where a quasi-stable flame could be established. A significant number of fine pale-white particles, believed to be

the higher-melting AN, evolved from the melt layer when no flame existed, but they were not observed once a flame was established. Other models have included the modeling of aerosol particles. Gas-phase processes for RDX and ADN were modeled with CHEMKIN as a one-dimensional, premixed flame. A kinetic mechanism consisting of 21 species and 110 reactions was compiled to model the deflagration of ADN. Additional work included the study of RDX, XM39, and M43 [362, 363]. The microprobe mass spectrometer (MP-MS) system was used to study the gas-phase chemical reactions occurring above solid propellant ingredients and actual solid propellants when they are heated and/or ignited by the heat flux from a CO₂ laser.

Using a tandem-flowing, afterglow-selected-ion flow tube, the basicity, reactivity, electron-binding energy, and collision-induced dissociation of dinitramide ion $[\text{N}(\text{NO}_2)_2]^-$ and nitroacetylide ion $[\text{O}_2\text{NC}\equiv\text{C}]^-$ were investigated [255]. Dinitraminic acid is among the strongest known gas-phase acids with $\Delta H^\circ_{\text{acid}} < 1297 \text{ kJ/mol}$ ($< 310 \text{ kcal/mol}$). The conjugate base, dinitramide anion, has a high electron-binding energy, is extremely unreactive, and is a very poor nucleophile. Collision-induced dissociation of dinitramide anion generated the $\text{O}_2\text{N}=\text{N}^-$ anion.

In laser-pyrolysis experiments under argon at 10–505 kPa (0.1–5 atm) with flux densities of 20–300 W/cm², the microprobe MS indicated only 1–1.5% or barely detectable NH₃ [363]. Three distinct regions of laser-induced decomposition were observed: **(1)** laser-induced pyrolysis (LIP), **(2)** laser-induced regression (LIR), and **(3)** laser-assisted combustion (LAC). LIP was observed at subatmospheric pressures and low heat fluxes ($< 50 \text{ W/cm}^2$). At or above atmospheric pressure and with higher heat fluxes, LIR (i.e., regression without a flame) could be observed. LAC required pressures of at least 303 kPa (3 atm) and heat fluxes of at least 100 W/cm². True ignition and self-sustained burning were not observed for any of the experiments. Of the three distinct categories of laser-induced behavior (LIP, LIR, LAC), the latter two categories were characterized by stable regression of the surface but with a luminous flame observed only for LAC. Under LIR conditions, ADN evolved N₂O, H₂O, N₂, NO₂, and NH₃ (in order of decreasing mol fraction) and numerous particles of AN. LAC was observed for ADN at 3 atm with an unstable flame, whereas tests at 5 atm produced a more stable flame with individual flamelets just above the surface. The flame produced significant amounts of NO and H₂O and a gas temperature of about 1350 K. During LIP, and before the onset of rapid pyrolysis, ADN bubbled vigorously, and primarily N₂O and H₂O and no other species were detected in the gas phase. After the onset of rapid pyrolysis, a fair amount of NO₂ and NH₃ along with small amounts of N₂ and NO were detected. At high pyrolysis rates, AN particles were thrown into the vapor space. The pyrolysis regression rate was relatively insensitive to incident heat flux. In addition to the MPMS system, direct and Schlieren photography were used to study the flame structure, and 25- μm thermocouples were used to measure the gas-phase temperature profile [364].

The thermal decomposition of ADN has been studied by thermal gravimetry combined with mass spectrometry (TG-MS) and by infrared spectroscopy [295]. Arrhenius parameters obtained from TG data by an isoconversional method are $E_a = 200 \pm 20 \text{ kJ/mol}$ and $A = 10^{21} \text{ s}^{-1}$. ADN decomposes entirely to gaseous products that have been identified by MS as NH_3 , H_2O , NO , N_2O , NO_2 , HONO , and HNO_3 . The infrared experiments showed that the primary decomposition products are N_2O and NO_2 . No evidence was found for the participation of dinitraminic acid as an intermediate in the reaction mechanism. Instead, a mechanism involving ionic reactions in the liquid phase is proposed. The fact that the same initial products have been observed over a wide range of temperatures (333–673 K [60–400 °C]) and heating rates (10^{-2} – 10^7 °C/s) suggests that this mechanism can be used to model the initial stages of combustion of ADN.

Vyazovkin and Wight [170, 296], in the range $T = 298$ – 523 K [25–250 °C] at a heating rate of 5 °C/min, found that NH_3 appeared only above 100 °C, much later than NO_2 and N_2O . NH_3 was not detected until 453 K [180 °C] in the TGA/FTIR analysis at a heating rate of 5 °C/min [293]. NH_3 and dinitramidic acid were possibly being absorbed in the condensed phase at low temperatures.

Probing mass spectrometry (PMS) is a very useful method based on microprobe and molecular-beam MS probing for the study of solid propellant flame structures at high (10 atm) and low (≤ 1 atm) pressures; it has been applied to the study of AP and ADN decomposition flames [365]. This apparatus allows the study of thermal decomposition of ADN or other oxidizers at high heating rates up to 100 °C/s under conditions approximately similar to those present in the condensed phase in the vicinity of the burning surface in a rocket motor. In this apparatus, a strand of burning material (propellant, pressed ADN pellet) is moving toward a stationary probe at a rate greater than the regression rate, and the probe measures a profile through the flame and dark zone. The ADN grains decomposed without flames at 101 and 303 kPa (1 and 3 atm, respectively) and with a flame at 606 kPa (6 atm). The regression rates were 3.4 mm/s at 1 atm, 12 mm/s at 3 atm, and 19 mm/s at 6 atm. Profiles of the species concentrations in ADN flames helped in identifying main reactions in high temperature zones of ADN decomposition at 1, 3, and 6 atm. In addition to flame studies, the non-deflagrating, non-flame thermal decomposition of ADN was investigated by molecular-beam MS on a sample that was heated rapidly from 433 K (160 °C) to 573 K (300 °C) with heating rates of 20 °C/s, giving a time-resolved profile of the products of ADN thermal decomposition and product release rates. A peak at $m/e = 72$ has not yet been identified and was tentatively assigned to nitramide H_2NNO_2 . There were no peaks at 106, 107, or 124, where one would expect the nitramide molecular ion or ADN clusters.

The structure of ADN combustion zones at 1–6 atm was studied using molecular-beam MS as well as a microthermocouple technique [355]. Three combustion zones were observed, and gaseous ADN was discovered in the first cool flame zone at 3 atm. Gaseous ADN dissociation to NH_3 and dinitraminic acid followed by dinitraminic acid

decomposition in the near-surface zone were key reactions, resulting in a temperature rise of about 150 K. The second high-temperature zone was found within 6–8 mm from the ADN burning surface at 6 atm. The main reaction in this zone was ammonia oxidation by nitric acid, and the combustion temperature was 1400 K. The third zone was observed at 40 atm, where the measured final temperature was ~2000 K. Based on these data, a chemical mechanism of reactions in both the ADN flame and combustion was proposed.

Mass spectrometric analysis of evolved gases during the decomposition of ADN revealed the formation of ions having a mass to charge m/e ratio of 17, 30, 44, and 46 amu [58]. Since ADN contains only nitrogen, oxygen, and hydrogen, the ions formed in the isothermal decomposition were identified as NH_3 , NO, N_2O , and NO_2 . The analysis of complete mass spectra showed that no other reaction products were observed. The other possible products looked for in the mass spectrometry included H_2O , HNO_3 , and HONO in the range of 10–250 amu, but none of those were observed. Figure 57 gives the TGA curve as well as the ion signal strength for the species detected, namely NH_3 (amu 17), NO (amu 30), N_2O (amu 44), and NO_2 (amu 46). The superimposed TGA trace of ADN shows that the majority of ADN decomposition takes place in the range of 413–493 K (140–220 °C). The

Figure 57: Mass spectrometric and thermogravimetric analysis of ADN decomposition products at a heating rate of 5 °C/min. (Reprinted and modified from [58] with permission granted by Dr. Santhosh 8 February 2021.)

mass spectral data show that the predominant species in the initial stage of ADN decomposition are N_2O and NO_2 , while those in the latter stage are NH_3 and NO . This is inconsistent with the thermal decomposition mechanism for ADN by Vyazovkin et al. [170].

4.8.2 Infrared Spectrophotometric Analysis of Intermediate Products

Mass spectrometry and IR spectrophotometry are the two primary fast-response methods used to analyze transient phenomena occurring on the surface of decomposing energetic materials. These methods can be applied to oxidizers by themselves, to formulated solid propellants, or to slabs of oxidizer sandwiched between two layers of fuel binder. The methods for rapid heating in either case can be a laser pyrolysis or the thin-film sample heating on a rapidly heated metal ribbon (T-jump/FTIR spectroscopy). The rapid pyrolysis chemistry of thin films of AN and ADN at temperatures approximating a burning surface was studied using T-jump/FTIR spectroscopy [334]. It is very valuable to study these two oxidizers next to each other using the same equipment because AN is one of the intermediate decomposition products of ADN. The sequence of appearance and amounts of each gas product combined with the net endothermicity and exothermicity of the process at each time gave the necessary information to develop multi-step reaction schemes. The decomposition of the condensed phase of AN is net endothermic up to at least 33 atm. Although dissociative sublimation and the formation of N_2O and H_2O dominate the overall process, the superposition of two additional reactions is needed to account for all of the products observed from AN. ADN becomes highly exothermic very early in the decomposition process. The superposition of two overlapping stoichiometric reaction branches explains this behavior. The spectra and thermal responses are consistent with the assumption that the reaction of NH_3 with NO_2 is the major source of heat released during the decomposition of AN above 33 atm and ADN at 1 atm and higher.

The decomposition mechanism

suggests that NH_3 evolution should occur early, but the experimental measurements have shown inconsistent results. When ADN was heated to 260 °C at a rate of 2000 °C/s on a platinum filament, FTIR detected NH_3 , N_2O , and HNO_3 in similar amounts in the initial spectra; then, the amounts of N_2O and NO_2 increased, and the amounts of NH_3 and HNO_3 decreased sharply [334].

Because HNO_3 may react with the inlet materials on a mass spectrometer and attach itself to the walls, MS is not the best method for detecting HNO_3 . FTIR seems to be more effective in detecting HNO_3 . Vyazovkin and Wight [170, 296] found that at $T = 50^\circ\text{C}$, HNO_3 evolved almost simultaneously with NO_2 , and its concentration increased.

4.9 Thermal Stability and Decomposition Reactions of Ammonium Dinitramide Solutions

The thermal stability of ADN solutions intended to be used as a liquid oxidizer was studied by microcalorimetry [366]. Additional heat evolution rate measurements were made with solid and liquid ADN mixtures containing Al powder, with and without addition of stabilizers [367], and with gelled ADN solutions [368]. Fumed silica is commonly used as a gelling agent for liquid oxidizers, but it may adversely affect the thermal stability of ADN solutions [369]. Several silica types have been investigated with regard to their compatibility with ADN: hydrophilic and hydrophobic silica, hydrophilic mixed oxide (SiO_2 and Al_2O_3), and very fine particle precipitated silica. Silica adsorption columns are used for separation of dinitramides from the mixture of reactants and by-products from which ADN is made.

4.9.1 Catalytic Decomposition of Ammonium Dinitramide Solutions

Although it is well known that dinitramides are energetic compounds, the thermal and catalytic decompositions of aqueous dinitramide solutions have not yet been studied extensively. In a study of the thermal and the catalytic decomposition of ionic oxidizers in aqueous solution such as ADN, HAN, AN, and HNF, the decomposition was followed by DTA-TGA, constant volume batch reactor and dynamic flow reactor coupled with a mass spectrometer [370]. The gaseous products were analyzed by mass spectrometry, whereas the condensed products were analyzed by Raman spectroscopy and acid-base titration to establish a balanced equation of the thermal or catalytic decomposition of these oxidizers. A 10% Pt/ Al_2O_3 / SiO_2 catalyst initially developed for HAN-water decomposition achieved only a low catalytic activity toward ADN-water mixtures. Other monometallic and bimetallic catalysts based on Pt, Fe, Cu, and Zn were prepared and tested to decompose these mixtures.

Binary HAN and ADN aqueous solutions have been decomposed thermally and catalytically [371]. Binary ADN/ H_2O mixtures were prepared with different concentrations: 75, 60, and 50 mass-% ADN. The catalysts were prepared by impregnation of alumina/lanthanum oxide with $\text{Cu}(\text{NO}_3)_2$, followed by calcination and characterized by transmission electron microscopy with a resolution of 3.5 Å, XRD, and hydrogen chemisorption. The decomposition processes were followed by DTA in a constant-volume batch reactor. In the constant-volume batch reactor, 50 μL of monopropellant was added to 80 mg of catalyst at room temperature under 1 bar of argon flow, using a micro syringe through a septum, and was then heated at a rate of 10 °C/min. The pressure and temperature were recorded versus time. This reactor can be used to simulate cold starts or injection by pulses, but not stationary monopropellant flow (steady-state studies). This work was done to study the effect of monopropellant concentrations on the activity of green propellants for rocket applications. The (10%)CuO/ Al_2O_3 / La_2O_3

+ 75% ADN mixture showed a lower onset of decomposition temperatures, higher reaction rates, and higher amounts of gas-phase products than other systems tested.

The thermal decompositions of solid ADN and aqueous ADN solutions were studied, and the products of decomposition were identified using a thermogravimetric analyzer connected to an FTIR spectrometer [372]. A study of the decomposition of aqueous ADN solutions in contact with CuO nanocatalysts showed that the decomposition of aqueous ADN was influenced by CuO nanocatalysts, leading to the formation of higher concentrations of NO_2 , which in turn autocatalyzed the remaining ADN decomposition.

4.10 Thermal Stability and Decomposition Reactions of Solid Mixtures Containing Ammonium Dinitramide

ADN can form eutectics and other solid solutions with a wide range of other oxidizers and energetic materials. These mixtures may have improved properties (increased explosive power, improved stability) than the ingredients by themselves.

Melting-point diagrams of binary mixtures containing ADN were described in Section 3.4.2. We will now look at the thermal stability of such mixtures with fuels and other oxidizers.

An ADN mixture that is of particular interest is that with AN. AN is an intermediate decomposition product of ADN and plays a major role in ADN decomposition. It has been observed that eutectic mixtures of ADN and AN decompose much faster than pure ADN.

DSC data showed that ADN in contact with AN was compatible up to 393 K (120 °C) [373]. A mixture of ADN with AP, however, was incompatible. This was confirmed by evaluating the neat ingredients and their mixtures using several different heating rates to obtain decomposition kinetics. A higher frequency factor and rate constant were found for the ADN/AP mixture compared to the neat ingredients, which indicated incompatibility.

Because decomposing ADN and other dinitramide salts are quite acidic, there is concern about their interaction with metals that are often added to solid propellants to increase specific impulse and suppress combustion instability.

The dinitramide salts of ammonia (ADN), hexamethylenetetramine (HDN), potassium (KDN), and sodium (NaDN) showed a linear relationship between the DSC rate of decomposition at the peak maximum and the slope value at the low temperature transition peak [374, 375]. As the cation basicity increased in the series $\text{ADN} < \text{HDN} < \text{KDN} \leq \text{NaDN}$, there was an increase in the low temperature transition peak, the energy barrier for dielectric relaxation, and the decomposition peak temperature, and there was a decrease in the loss tangent $\tan \omega$ value at the low temperature transition peak, specific heat capacity, and the rate and enthalpy of decomposition. Five aluminum powders of different surface areas were analyzed by DSC in platinum sample

pans, and it was found that the enthalpy and rate of oxidation increased as the particle size of Al decreased, whereas the enthalpy of the Al melt decreased. TGA showed a two-step weight gain in the oxidation of Al, with plateaus in the 338 K (65 °C) and 386 K (113 °C) regions, and the percent weight gain increased as the particle size of Al decreased. Variable DSC and TGA heating-rate studies showed that the activation energies for the first step in the oxidation process increased as the particle size of Al increased.

The thermal decomposition of ADN/potassium dinitramide (KDN) mixtures was investigated by combined thermogravimetry-differential thermal analysis (TGA-DTA) and compared to the decomposition of the two salts by themselves [376]. ADN melts at 364 K (91 °C) followed by a single-step decomposition (100%) in the temperature range of 408–493 K (135–220 °C). KDN melts at 403 K (130 °C) prior to a two-stage decomposition reaction, with an onset of decomposition at 433 K (160 °C). The mass loss corresponding to the first stage was ~38%. The non-isothermal decomposition of ADN, KDN, and mixtures of KDN/ADN (90 : 10, 50 : 50, 25 : 75, 10 : 90 ratios by mass) was studied at a heating rate of 5 °C/min. The kinetic parameters, such as activation energy E and the logarithm of the pre-exponential factor A , for the thermal decomposition reactions were evaluated by two integral equations (Coats-Redfern, Madhusudanan-Krishnan-Ninan) for comparison. The calculated activation energy was 120 kJ/mol for ADN and 143 kJ/mol for KDN, while that of the mixtures was in between, and the corresponding $\ln(A)$ values were ~35 and 25 min⁻¹.

One of the ADN mixtures of particular interest is the mixture of ADN and guanurea dinitramide (GUDN). GUDN can be used to separate dinitramide ion from the reaction mixture and can later be converted to other dinitramide salts. The thermal decomposition kinetics of a mixture of ADN and GUDN were studied by non-isothermal differential scanning calorimetry [377]. An isoconversional method is a method to measure activation energies by taking timed data points at the same level of conversion α instead of doing isothermal tests and repeatedly measuring α as a function of time. Advanced isoconversional methods were used to investigate the dependence of activation energy (E_a) on conversion (α). A strong dependence of E_a on α was observed, indicating a complex decomposition process. E_a is close to 165–175 kJ/mol at the start of the reaction, and then reaches a maximum of ~196–199 kJ/mol at $\alpha = \sim 0.4$, followed by a strong decrease to ~135 kJ/mol near the end. The results suggest that the decomposition of ADN greatly influences the observed E_a dependence on α . This was further supported by FTIR results and enthalpy values of the exothermic decomposition.

ADN crystals, prills, and two ADN-based propellants having different relative amounts of ingredients were characterized by DSC, TGA-DTA-FTIR-MS, ARC, heat flux calorimetry, and isothermal nanocalorimetry [378]. Decomposition of ADN was observed in all of the samples at temperatures above the melting point of ADN (~365 K = ~92 °C). Formation of N₂O, NO₂, H₂O, CO₂, CO, N₂, and NO was detected during the ADN decomposition. Even at temperatures below the melting point of

ADN, early solid decomposition of ADN, which generated N_2O and H_2O , was detected at 333 K (60 °C).

4.10.1 Stabilizers for Ammonium Dinitramide

Although pure solid ADN has sufficient thermal stability to be used as an oxidizer in solid propellants (or in dissolved form in liquid monopropellants), the effect of minute contaminants that might catalyze the decomposition and lower the thermal stability can be counteracted by the addition of stabilizers. Numerous stabilizers have been evaluated for this purpose, similar to the search for stabilizers for HAN. Since the first step of ADN decomposition is a proton transfer and formation of free, unstable dinitramidic acid, it was proposed that basic additives such as urea, hexamethylene tetramine, cyanoguanidine, or tetraethylenepentamine/acrylonitrile (HX-879, TEPAN) should inhibit the dissociation and stabilize the ADN [379, 380].

Because ADN has a higher energy content in comparison to AN, the exothermic decomposition already takes place under low pressures. Fortunately, phase transitions effecting changes in volume and density are lacking. Suitable additives are required for an effective stabilization of ADN at lower temperatures. The thermal stability of pure ADN and ADN with 2% of different stabilizers was investigated using DSC and TGA [381]. The DSC measurement showed melting onset at 91.5 °C followed by thermal decomposition all the way up to 200 °C. Although the addition of 2% MgO (usually effective for AN) or NaBO_2 showed no effect, the addition of 2% urotropine (hexamethylenetetramine), 2-nitrodiphenylamine (often used for double-base propellants), or akardite II (methyldiphenylurea) shifted the onset of ADN thermal decomposition to higher temperatures.

Prophosphatranes are adamantane-like spherical molecules in which the bridge joints are nitrogen and/or phosphorus atoms. Prophosphatranes have been patented as stabilizers for ADN and other dinitramide salts [382].

Prophosphatranes have been described in which R' , R'' , and R''' are the same or different substituents such as aryl or alkyl groups.

In search of stabilizers for molten ADN, at first the decomposition mechanism was studied by using ^{15}N isotope-labeled ADN with the isotope markings in the cation or the anion [383]. ADN with the ^{15}N label in the NH_4^+ cation was prepared by neutralizing a 2% solution of HDN in ether with liquid ammonia (97% enriched in $^{15}\text{NH}_3$) at 233 K (−40 °C). The crystals were washed with ether and recrystallized from isopropanol. ADN with the ^{15}N label in the anion was prepared by reaction of acrylonitrile

with $^{15}\text{NH}_3$ and nitration of iminodipropionitrile. Then 0.5-g samples of ADN were evacuated and sealed in glass ampules and immersed in a constant temperature bath at 120 °C for test durations from 30 min to 10 h. The gas released from the ampules was analyzed by GC and MS. Residual nitrate was analyzed spectrophotometrically after the residue was dissolved in water, and nitric acid was measured by pH. The experiments were then repeated with various stabilizers, including 0.78% potassium bromide, 0.58% potassium iodide, and various organic amines, carboxylic acids, and amides, as well as their dinitramide salts (22 different compounds tested). The most effective reduction of the gas-evolution rate was achieved by the addition of 1 mol-% hexamethylene tetramine, semicarbazide, oxalylhydrazide, aminotriazole, urea, or 1H-benzotriazole. In the decomposition of ADN with the ^{15}N label in the cation, current understanding of the decomposition mechanism would lead one to expect that half of the nitrogen atoms in the N_2 formed come from the ammonium cation and the other half is derived from the anion. The experiments showed that the percentage of ^{15}N in the N_2 formed increased with progression of the decomposition reaction, starting at 40% and ending at 90%. In the decomposition of ADN with the label in the anion, the ^{15}N label was found mostly in N_2O , which evolved only in the form of $^{15}\text{N}^{14}\text{NO}$ and only a little in N_2 and NO . The ratio of $\text{N}_2\text{O} : \text{N}_2$ changes during progressing decomposition. Initially the amounts are the same, but then the rate of N_2O evolution increases while that of N_2 evolution remains the same. The oxidation of the ammonium cation is responsible for the formation of N_2 and an autocatalyst. It was hoped that the addition of readily oxidizable stabilizers would scavenge the autocatalyst and prevent oxidation of the NH_4^+ cation.

The isothermal decomposition rates of ADN were measured at 333, 343, 353, and 363 K (60, 70, 80, and 90 °C, respectively) by measuring the amount of AN and N_2O formed by their UV absorption [384]. The tests were then repeated at 363 K after the addition of 1–2 mass-% of stabilizing additives, such as KDN, KF, a phenylphosphorus polymer, or perhydro-1,3,5-triazine-2,4,6-trione (also known as Verkade superbase). Hexamethylene tetramine was also considered as a potential stabilizer. Perhydro-1,3,5-triazine-2,4,6-trione was found to be the most effective additive, but KF showed no effect, and KDN worsened the stability. Free radical scavengers such as 2,2-diphenyl-1-picryl hydrazyl did not improve the stability of ADN, but 2-nitro-diphenylamine (commonly used as a stabilizer in double-base propellants) slowed the rate of decomposition somewhat.

Several stabilizers were evaluated for solid and liquid ADN mixtures containing Al powder [367] and for gelled ADN solutions [368]. See also [293]. Stabilizers that are free radical scavengers (e.g., butylhydroxytoluene) showed no beneficial effect on ADN decomposition; 2-nitrodiphenylamine, widely used as a stabilizer for double-base propellants, at the 1% level inhibited N_2O formation at 348 K (75 °C) for the first 6 h, but once it was depleted, the ADN decomposition proceeded uninhibited.

ADN has a more positive enthalpy of formation, 1208 versus –2518 J/g, and a higher heat of explosion than AP, 3337 versus 1972 J/g. One disadvantage of ADN is its much

lower thermal stability compared to that of AP. If it is possible to find stabilizers, ADN could be considered as a substitute candidate for AP. An extensive investigation was made with eight substances to find out their stabilization effect on ADN [385, 386]. ADN was mixed with 12 mol-% of each of these candidate stabilizers, and mass loss as function of time and temperature at 338, 343, 348, and 353 K (65, 70, 75, and 80 °C, respectively) and adiabatic self-heating was measured by isothermal TGA. The stabilization effectiveness changed with temperature. With well-stabilized solid-phase ADN, the rate-determining step was N—N bond cleavage in the dinitramide anion. In unstabilized ADN, the protonation of hydrogen dinitramide accelerated its decomposition autocatalytically. Various other organic and inorganic compounds were tested as stabilizers for ADN [387]. MgO, SiO₂, and hexamethylenetetramine did not show any improvements, but TiO₂, *N*-methyl-*p*-nitroaniline, and 2,4,6-triaminopyridine did have some stabilizing effect.

All ADN stabilizer candidates that work to any extent are weak to moderately strong bases, capable of reaction with acid moieties. ADN-stabilizing additives are also capable of reacting with NO_x and sequestering it before it can do any more damage. Pyridine and pyridone have been described as stabilizers for hydroxylammonium nitrate (HAN) and hydroxylamine in U.S. patent 5703323 (Rothgery et al. [388]), and similar compounds have been evaluated for stabilization of ADN [389]. Other stabilizers claimed are purine, pyrimidine, and triazine derivatives such as aminopyridines, aminopyrimidines, aminopyrazines, aminotriazines, aminoquinolines, aminoquinoxalines, aminocinnolines, aminopteridines, aminoacridines, and aminophthalazines.

ADN that is intended for melt casting (as well as in mixtures with aluminum powder) can be stabilized by the addition of 1% MgO [139].

The effect of four different stabilizers, by themselves and in various mixtures with each other, on the thermal decomposition of ADN and the interaction between ADN and NC was measured using DSC [264]. The candidate stabilizers included *N*-methyl-*p*-nitroaniline (MNA), 1,3-dimethyl-1,3-diphenylurea (C2), 2-nitrodiphenylamine (2-NDPA), and hexamethylenetetramine (HMT) and their mixtures MNA/C2, MNA/2-NDPA, and MNA/HMT. The results showed that the interaction between ADN and NC can be retarded to a certain extent by mixing MNA and C2, and the nascent interaction between ADN and NC can be inhibited by mixing the complex of MNA/C2, MNA/2-NDPA, and MNA/HMT.

4.10.2 Catalyst-Enhanced Decomposition of Solid Ammonium Dinitramide

The effect of catalysts on thermal decomposition of ADN is studied for several reasons: There are many unwanted contaminants that can have an adverse catalytic effect on the thermal decomposition of ADN. One needs to know which of these contaminants are the worst actors in order to prevent premature decomposition of ADN. On the other hand, we are looking for catalysts that can enhance the burning rate of ADN-based

solid propellants (Section 4.11.1 and a future volume on solid propellants). Some of these catalysts may even be useful for the decomposition of ADN solutions in liquid monopropellants.

The effects of ten different combustion catalysts on the thermal decomposition of ADN were studied using DTA and TGA experiments under linear temperature-increase conditions and isothermal TGA conditions [390]. The kinetic parameters of the thermal degradation of ADN and mixtures of ADN and catalysts were calculated for the DTA results at heating rates of 2, 5, 10, or 20 degrees per minute. The results showed that the catalysts containing Fe or Cu (except Fe_2O_3) distinctly affected the thermal decomposition of ADN and caused a decrease of the thermolysis peak temperature and an increase of the rate of mass loss of ADN. The effects of the catalysts containing Cu were more salient, and their catalytic mechanism can be attributed to coacervation phase catalysis, while the catalytic mechanism of the catalysts that contain Fe is a type of gas-phase catalysis. In contradistinction, additives containing ammonium salts or Ca achieve better thermal stability during the thermal decomposition of mixtures of ADN/additives as a result of the NH_3 produced, which absorbs protons. They shift the thermolysis peak temperature (T_p) to a higher temperature and increase the activation energy (E_a) of ADN, restraining the thermal decomposition of ADN.

Monodispersed cobalt metal nanoparticles were prepared by means of a hydrogen arc plasma method in an inert atmosphere and were characterized by particle size, morphology, and specific surface area [391]. ADN samples containing varying amounts of Co nanoparticles were prepared, and the effect of different Co nanoparticle concentrations on the decomposition of ADN was investigated using DTA. The decomposition exotherm peak temperature of ADN decreased with increasing Co addition, which indicated that the Co nanoparticles have a strong catalytic effect on ADN decomposition.

Copper(II) oxide is not a normal contaminant of ADN, but it may be added for other reasons, for instance as a burning-rate catalyst. Copper(II) oxide has been added to AN for phase stabilization, but ADN does not undergo phase changes at room temperature as AN does. The effect of copper(II) oxide on the thermal decomposition of ADN was investigated to gain a better understanding of the thermal decomposition mechanism of ADN [392]. The thermal behavior and activation energy associated with the decomposition of ADN/CuO mixtures were analyzed using sealed-cell DSC. DSC results showed that CuO affects the thermal stability of ADN and promotes its decomposition. TGS/DTA-evolved gas analysis was also performed, and in addition, the decomposition behavior was observed visually using hot-stage microscopy. From the results, a thermal decomposition mechanism was proposed for ADN/CuO. In this mechanism, copper dinitramide $\text{Cu}[\text{N}(\text{NO}_2)_2]_2$ is generated at the surface of the CuO almost simultaneously with the melting of the ADN. Next, a significant exothermic reaction occurs, associated with the decomposition of $\text{Cu}[\text{N}(\text{NO}_2)_2]_2$, followed by decomposition via $[\text{Cu}(\text{NH}_3)_2](\text{NO}_3)_2$ and $\text{Cu}(\text{NO}_3)_2$.

4.11 Combustion of Ammonium Dinitramide

This section describes the laboratory studies of the linear rate of combustion of ADN by itself in the absence of any fuel. Later sections also describe the combustion of ADN with fuel additives or with binders. The combustion of ADN by itself in the absence of any fuel is sometimes also called self-deflagration.

ADN burns without any luminous emission at low pressure, forming copious white vapors that condense as a fine white powder inside the tube and on the cold surfaces of the bomb. As the pressure increases, small flamelets emanating from local hot spots can be observed. Above 1–2 MPa, the gases become almost transparent, a luminous flame appears, and the condensed products of (partial) combustion are no longer observed. The burning-rate data display a considerable scatter, especially in the pressure range below 10 MPa.

According to several authors [353, 393, 394], ADN is capable of sustained burning at atmospheric pressure, whereas according to Denisjuk, Kuleshova, and Shepelev [395], ADN does not burn at pressures below 0.5 MPa. Sinditskii [396, 397] failed to obtain self-sustained burning of pure ADN at atmospheric pressure either by decreasing the sample density to 1.35 g/cm³ or by increasing the sample diameter to 12 mm. A sample 12 mm in diameter and 14 mm in height, having a density of 1.67 g/cm³, burned through a length of only 8 mm but then extinguished. Even at an initial temperature of 353 K (80 °C), samples of pure ADN were incapable of complete burning at atmospheric pressure. Samples of molten ADN at a temperature of 373 K (100 °C), however, were capable of complete burning, with the burning rate varying from 6.7 to 9.1 mm/s [293, 361, 363]. All of these investigators observed the emission of a solid aerosol of AN above the surface of burning ADN [334], noted a white cloud of AN particles leaving the surface of ADN during their pyrolysis studies, but attributed its appearance to the recombination of NH₃ and HNO₃ upon entering the cool-gas phase. They postulated that AN would not be present if combustion were taking place because NH₃ and HNO₃ would decompose to other species instead of recombining to AN.

Sinditskii et al. [397, 398] observed profuse amounts of white vapor that condensed as a fine white powder inside their experimental apparatus and at cold surfaces of their constant-pressure window bomb. After examining the white powder, they noted that it consisted not only of AN but also of some ADN.

4.11.1 Strand Burning Rates of Ammonium Dinitramide

Strand burning of ADN by itself in the absence of any fuel is sometimes also called self-deflagration. In most experiments, the burning behavior of this new oxidizer is compared to that of the most frequently used oxidizer, AP.

4.11.1.1 Experimental Studies of Solid ADN Strand Burning

At low pressure, ADN burns without any luminous emission, forming copious white vapors that condense as fine white powder at cold surfaces of the bomb. As pressure increases, small flamelets emanating from local reaction sites are observed, and above 1–2 MPa, flowing-off gases become almost transparent. Above 2 MPa, a luminous flame appears, resulting in elimination of the condensed combustion products. Nevertheless, photographic records frequently reveal segments with a lack of luminescence, suggesting that the flame is not very stable and often exhibits random patterns. Burn-rate data display a considerable scatter, especially in the pressure range below 10 MPa. The appearance of a region of strongly pronounced data scatter is indicative of combustion instability at these pressures.

In some sandwich burner experiments, ADN was able to burn by itself, leaving the unburnt fuel lamina behind if a non-energetic binder had been used instead of an energetic binder [399, 400]. More of these experiments will be discussed in a future volume on solid propellants.

The combustion behavior of ADN was studied in the form of both pressed strands and single crystals [401]. Self-sustained combustion of ADN pressed into plexiglass tubes 4 mm in internal diameter was found to begin at 0.2 MPa. Within the pressure intervals of 0.2–1.5 and 10–36 MPa, the combustion process was stable, whereas at 2.8 MPa and below the burning rate turned out to be unsteady through the length of the strand, and its value might vary by more than twice the rate at the same pressure. Small amounts of paraffin added to ADN substantially reduced the low-pressure limit of ADN combustion to the subatmospheric region. The temperature distribution in the ADN combustion wave was measured at 0.1–4.1 MPa using thin bare tungsten-rhenium thermocouples. The ADN decomposition reaction in the condensed zone to form AN and N_2O is supposed to play a dominant role in burning at low pressures. The ADN surface temperature corresponds to the temperature of AN dissociation to yield NH_3 and HNO_3 . Heat feedback from the gas to the surface is negligibly small. Temperature measurements suggest that the flame structure of ADN is subdivided into three zones. Thermocouple-aided experimental studies on the combustion of different energetic materials have shown that the surface temperature is equal to the boiling point or, in the case of salts like ADN, the dissociation temperature [402, 403].

The self-deflagration of pressed pellets of ADN was studied in preparation for later experiments with the combustion of sandwiches with ADN laminae on both sides of a binder lamina [404]. Results obtained with ADN were then compared to those obtained with AP. Burning-rate measurements of ADN obtained from three different sources resulted in quite different curve shapes when the burning rate versus pressure was plotted on double-logarithmic graph paper. In comparison to AP, all three ADN samples burned faster, and the slope was less steep.

ADN from three different sources was recrystallized from isopropanol and compacted into 7-mm polycarbonate tubes under a pressure of ~250 MPa, and the burning rate was measured between 0.5 and 30 MPa [395]. The burning-rate curve as a function

is very complex and consists of four different regions with quite different pressure exponents (Figure 58). In the range of 0.5–4 MPa, the burning rate increased with a pressure exponent of 0.55. In the range of 4–6 MPa, the burning rate decreased, and the slope was -0.55 . Between 6 and 10 MPa there was little change of the burning rate, and beyond 10 MPa (data available up to 30 MPa) it increased again, and the pressure exponent was 0.48.

Figure 58: Burning rate of ADN and ADN mixtures. (Reprinted and modified from [395]; Reprinted with permission from Pleiades Publishing Inc.)

At all pressures, the charges burned to the end and left a whitish residue on the walls. The residue has been analyzed and consists mostly of AN with a little undecomposed ADN. In the vicinity of the burning-rate maximum, the combustion was very unsteady, and the burning rate fluctuated between 45 and 70 mm/s. The burning rate, particularly in the area of the burning-rate maximum, is very sensitive to additives. Adding 0.2 to 0.5% of polymethylmethacrylate (PPMA) powder or 1.5% fumed silica eliminated the up-and-down behavior and allowed the burning-rate data to fit nicely on a straight line, as the Robert deVeuille law would predict.

The burning rate of ADN is also very sensitive to moisture. Leaving the ADN exposed to air (20 min at 293 K and 90% relative humidity) caused the ADN to pick up moisture, and the maximum burning rate of the pressed samples was decreased by 15%. Leaving the ADN out in moist air for 240 min caused it to gain 2.5% by weight, the burn-rate maximum disappeared, and the straight line was shifted downward. Surprisingly, even ADN with very high water content was still capable of burning at high pressures. A sample with 8% H_2O had a paste-like consistency and burned with a regression rate of 11 mm/s at 4 MPa. An aqueous solution containing 75% ADN burned with a regression rate of 4 mm/s at 4 MPa. The temperature profile through the combustion zone was measured with a thermocouple probe. At 0.5 MPa, the temperature close (1 mm) to the solid surface was ~ 950 K, and at a greater distance (6 mm) it

was ~1300 K. ADN burns much faster than other propellant ingredients. For instance, at 2 MPa, it burns twice as fast as RDX and 14 times faster than AP.

Data on ADN combustion were obtained in 1976 in the Soviet Union but could not be published at that time. These data eventually surfaced in 1999 [393]. Strands were prepared by pressing ADN under a pressure of 300 MPa into polymethylmethacrylate (PMMA) tubes with a wall thickness of 1 mm and a length of 20 mm. The burning rates were measured in a combustion bomb at nitrogen pressures up to 10 MPa. The temperatures in the burning wave were measured with W-Re thermocouples with a wire diameter of 5 μm . The temperature results are summarized in Table 20.

Table 20: Flame temperature characteristics of ADN combustion.

Pressure MPa	Burning rate r_b (measured experimentally) cm/s	Temperature (measured experimentally)	
		Surface temperature K	Flame temperature K
0.066	0.22	530	685
0.1	0.27	560	720
2	1.82	700	2640
6	2.26	715	2770

Data source: [393]

The samples of ADN burned steadily at room temperature throughout the range of pressures studied (0.025–10 MPa). At pressures of up to 1 MPa, combustion proceeded without a luminous flame, but with the formation of a great amount of white smoke (AN). Above this pressure, a bright flame became visible. At a pressure of 2 MPa, a high-temperature zone, separated from the surface by a dark zone, appeared. The heat released as a result of ADN decomposition in the condensed phase was consumed in heating the substance and for subliming the decomposition product AN. However, as estimates showed, the heat was insufficient for a complete evaporation of AN, and some of it escaped as smoke. AN did not decompose under the conditions of ADN decomposition in the condensed phase, and the rate constant for AN decomposition was four orders of magnitude smaller than that of ADN. The dependence of the burning rate of ADN on pressure is shown in Figure 59.

The burning rates were very similar for the samples of 5 and 7-mm inner diameters at 0.025–2 MPa and could be described by Robert-deVielles law with a pressure coefficient of about 0.7, but above 2 MPa the curves for samples with different diameters diverged. The combustion peculiarities of ADN correlated with high rates of ADN decomposition, low reactivity of gas products, and the formation of a large amount of intermediate product (AN) at low pressures. Cu_2O accelerated ADN combustion, whereas Al and AN slowed it down, sidetracking the heat needed for heating up the

Figure 59: Strand burning rate of ADN pellets pressed into tubes with different internal diameters. (Republished and modified from [393], with permission of © 1999 Elsevier; permission conveyed through Copyright Clearance Center, Inc.)

reactants and sustaining endothermic processes. However, the very marked inhibiting effect of small amounts of organic materials on ADN combustion was a surprise. The addition of AN to ADN caused a strong decrease in the burning rate even at small concentrations of this additive, but the burning-rate retarding effect of AN diminished at the higher pressures; see Figure 60.

The thermal structure of combustion waves of ADN was profiled by W+5Re/W+20Re microthermocouple techniques and enhanced by data processing [394]. Temperature profiles and burning wave parameters (burning rate, burning surface temperature, heat feedback from gas to solid, heat release in solid, zone dimensions and temperatures in solid and gas phases) were obtained for ADN samples at pressures of 0.1–8.08 MPa (1–80 atm) and at sample temperatures of 123 K (–150 °C), 293 K (20 °C), and 353 K (80 °C) in nitrogen atmosphere. Characteristic features of the physics of ADN combustion are a large heat release in the solid phase and a weak heat feedback from gas to solid (due to low emissivity of the flame), low burning surface temperatures, and the two-zone structure of the gas phase above the solid (molten) surface. A surprising observation was irregular temperature pulsations (~5 Hz) in the gas phase; however, temperature traces are smooth in the solid phase. At 101 kPa (1 atm), averaged temperature profiles had only one zone in the gas phase, with a dark zone temperature of 723 K (450 °C). Only at pressures greater than 101 kPa (1 atm) did a two-zone structure in the gas phase develop. The mass burning rates $\dot{m}$ and surface temperatures T_s for burning ADN at three different initial sample temperatures and seven chamber pressures are summarized in Table 21.

Figure 60: Effect of AN addition on the strand burning rate of ADN. (Republished and modified from [393], with permission of Elsevier; permission conveyed through Copyright Clearance Center, Inc.)

Table 21: Mass burning rates $\dot{m}$ and surface temperature for burning ADN.

Initial temperature			Pressure, atm						
°C			1	3	5	10	20	40	60
-150	$\dot{m}$	$\text{g cm}^{-2} \text{s}^{-1}$	0.32	0.43	0.56	0.80	1.32	2.4	3.4
	T_s	°C	260	270	279	294	312	342	355
+20	$\dot{m}$	$\text{g cm}^{-2} \text{s}^{-1}$	0.63	1.83	2.5	3.9	4.2	4.5	4.8

Data source: [394]

The macrokinetic law of ADN gasification in combustion waves has the form

$$m = 13.6 \times 10^6 \exp(-38000/2RT)$$

where T is the temperature in kelvin and m is the mass burning rate in $\text{g cm}^{-2} \text{s}^{-1}$.

The strand burning rates of ADN were compared to those of HNF, RDX, HMX, CL20, and AP [405]. Samples of ADN powder were dry-pressed at 621 MPa and held for

10 min. The density of the resulting rectangular pellets was 97–98% of the theoretical maximum density. The sample sources of ADN consisted of small batches synthesized at the U.S. Naval Air Warfare Center, Weapons Division, as well as a sample from SRI International.

The ADN burning rates at ambient temperature are quite high, with a relatively low burning rate pressure exponent; however, the data displayed considerable scatter in the pressures between 2 and 10 MPa. The ambient temperature ADN data are compared to those of Fogelzang et al. [401] in Figure 61, where the data scatter is also observed. Fogelzang et al. attributed this data scatter to unstable combustion, but it may also be due to the deconsolidation and spalling of the material due to thermal stresses in the crystalline sample.

Figure 61: Strand burning rate of ADN at room temperature; comparison of U.S. Naval Air Warfare Center Weapons Division and Mendeleev University Russia data. (Republished and modified from [406] with permission of American Institute of Aeronautics & Astronautics; permission conveyed through Copyright Clearance Center, Inc.)

ADN burning rate data at two initial temperatures (298 K, circles; 348 K, triangles) over the pressure range of 0.69–10.3 MPa are presented in Figure 62. There is a significant amount of data scatter, and it takes a good amount of imagination to recognize a linear trend in these data.

Figure 62: ADN strand burning rate data at two initial temperatures. (Republished and modified from [406] with permission of American Institute of Aeronautics & Astronautics; permission conveyed through Copyright Clearance Center, Inc.)

In extending conventional burning-rate and pressure-exponent measurements, additional data were used to determine the temperature sensitivity coefficient σ_p of the burning rate of ADN and four other oxidizers [406]. The simplest means of determining a value of σ_p is to measure the burning rate of a particular material as a function of initial temperature, take the natural logarithm of the burning rate values, and determine the burning-rate temperature sensitivity as the slope of the line through a plot of the natural logarithm of the burning rate versus the initial temperature. The main requirement is to obtain a consistent and reliable set of burning rate data at various initial temperatures and pressures. In the case of ADN, the temperature sensitivity decreases with increasing pressure. A comparison of the temperature sensitivity coefficients of ADN and AP is shown in Figure 63. The temperature sensitivity coefficient of ADN decreases, while that of AP goes through a minimum.

Previously, at 1–6 atm, only two zones had been observed in the flame front of ADN combustion [401]. Then the work was extended to 4 MPa (40 atm) chamber pressure, and a wide third zone was detected and studied using probing mass spectrometry and microthermocouples [407]. Pressed ADN pellets 10 mm in diameter and 15 mm high were burned in an argon atmosphere. A cooled stainless steel probe was inserted

Figure 63: Comparison of the temperature sensitivity coefficients of the burning rates of ADN and AP. (Republished and modified from [406], with permission of © 1999 American Institute of Aeronautics and Astronautics; permission conveyed through Copyright Clearance Center Inc.)

into the flame, and gas samples were drawn into a mass spectrometer. The probe was moved from 1.2 to 16 mm above the surface of the burning ADN pellet, and intensity profiles for key fragments at m/e of 28, 30, 32, and 44 amu were recorded. A decrease in N_2O concentration and an increase in N_2 and O_2 concentration were observed within a zone that is 8–10 mm wide. The NO concentration did not vary a lot within this zone. At the same time, temperature profiles were measured using un-sheathed Pt/Pt10Rh microthermocouples that were only 50 μm in diameter. The temperature increased from 1400 to 1800 K from 1.5 to 8 mm above the burning surface at 4 MPa (40 atm). It was attempted to reproduce the species and temperature profile using the CHEMKIN code with 170 reactions for 29 species. Experimental data and calculated numbers showed satisfactory agreement. The calculated adiabatic temperature at a sufficient distance from the surface was close to that expected for thermodynamic equilibrium.

Samples of pure ADN and ADN mixtures with paraffin were prepared by pressing strands with $40 \times 5 \times 5$ -mm dimensions [408–410]. The mixture (mass ratio 90 : 10) corresponded to the maximum specific impulse. The burning rates were measured in the pressure range from 0.1 to 10 MPa. Above 2 MPa, the burning rates of ADN were close

Figure 64: Burning rates of ADN and ADN/paraffin strands. (Republished and modified with permission of American Institute of Aeronautics and Astronautics, Inc. from [410]; permission conveyed through Copyright Clearance Center, Inc.)

to those of ADN/paraffin mixtures but unexpectedly exceed those above 4 MPa where the two curves cross each other (Figure 64). Similar data are presented in Figure 68 and 69.

In addition to burning-rate measurements, UV and IR spectra of flame zones allowed the identification of reactant profiles through the length of the flame zone, which were then compared to theoretical predictions based on kinetic models. Burning of ADN starts with the decomposition of the material at the surface, followed by chemical reactions in the gas phase. Therefore, the burning of ADN would have to be modeled by two separate reactions. The results of CHEMKIN calculations for the gas-phase reaction at 1100 K are shown in Figure 65.

It is interesting to compare the peculiar behavior of ADN deflagration with that of other ammonium salts of oxidizing acids, AN and AP, [411] and with dinitramide salts of other bases [412]. Burn-rate studies were carried out on dinitramide salts of common formula of $L_n\text{HN}(\text{NO}_2)_2$ (where $n = 1$ or 2 ; L = methylamine, trimethylamine, *tert*-butylamine, tetramethylammonium, urea, guanidine, aminoguanidine, triaminoguanidine, ethanolamine, diethanolamine, ethylenediamine, hexamethylenediamine, aniline, 3-nitroaniline, 2-toluidine, benzylamine, phenylhydrazine, morpholine, piperazine, pyridine, 3,5-dimethylpyridine, or 5-aminotetrazole), as well

Figure 65: Calculated temperature and species profiles for pure ADN combustion. (Republished and modified with permission of American Institute of Aeronautics and Astronautics, Inc. from [410]; permission conveyed through Copyright Clearance Center, Inc.)

as lithium and barium salts of dinitramide. Most of the salts exhibited either combustion instability (like ADN) or a transition region on their $r_b(p)$ curves. The occurrence of this region depended on the fuel reactivity and, largely, the surface temperature, which was assumed to be dissociative and dependent on the amine basicity. In order to study the combustion mechanism, the flame structure of hexamethylene diamine bis(dinitramide) was investigated with tungsten-rhenium microthermocouples. The burn-rate study of this compound over a wide initial temperature range was used to evaluate the temperature sensitivity of the combustion rate.

The relationships between ADN burning rate and pressure were examined by measuring combustion phenomena under different pressure conditions in a combustion bomb [413]. Experimental temperature profiles in ADN combustion waves were taken with thermocouple probes in an effort to identify initial thermal decomposition reactions and dark-zone formation mechanisms in ADN combustion. At atmospheric pressure, the decomposition temperature barely exceeds 800 K, and the profile is flat out to 10 mm away from the surface, but above 2 MPa, a high temperature zone appears between 5 and 12 mm from the surface.

ADN is unique among the ammonium salts in that its autodecomposition can proceed even at subatmospheric pressures. Chemical analysis of the decomposition products at subatmospheric pressures showed that the amounts of NO, N_2O , NO_2 , and HNO_3 remain constant over the lower pressure range, and the proportions of NH_4NO_3 ,

NH_4NO_2 , and $\text{NH}_4\text{N}_3\text{O}_4$ decrease with increasing pressure. The stoichiometry of ADN decomposition at subatmospheric pressures can be approximated by the following equation:

In spite of the efforts by many investigators, there still remain a number of unresolved issues about ADN combustion. In particular, a well-grounded theory needs to be established to help in understanding the irregular burning phenomenon in the pressure range of 2–10 MPa (20–100 atm).

ADN combustion is stable in the range from 0.5 to 2 MPa (5–20 atm), and the pressure sensitivity of the burning rate has the form

$$r_b = 20.72p^{0.604}$$

where r_b is the burning rate in mm/s and p is the pressure in MPa [288]. This equation is valid for the pressure range from 0.5 to 2.0 MPa. The burning characteristics are controlled by exothermic decomposition in the condensed phase. Above 10 MPa (100 atm), the burning rate is well correlated with pressure as

$$r_b = 8.50p^{0.608}$$

where r_b is the burning rate in mm/sec and p is the pressure in MPa. This equation is valid for the pressure range from 10 to 36 MPa. Combustion of ADN pressed grains is stable, and intensive heat feedback from the gas phase dictates the burning rate. The pressure dependence of the burning rate, however, becomes irregular in the range of 2–10 MPa (20–100 atm). This phenomenon has been attributed to the competing influence of the condensed-phase and gas-phase exothermic reactions in determining the propellant surface conditions and the associated burning rate.

ADN and hexamethylenediamine(2+) dinitramide (HMDADN) both have a condensed-phase combustion mechanism that may be responsible for occasional combustion instability [414]. The Zeldovich and Novozhilov criteria have been calculated for these two salts in an effort to explain the combustion instability.

In spite of the fact that ADN is an oxidizer, combustible surroundings have been found to exert practically no effect on the burning rate of ADN pressed strands. In contrast, minor amounts of organic and inorganic additives intimately mixed in were found to have a strong effect on ADN burning behavior, extending considerably the pressure limit of sustained combustion to the vacuum area [397]. Burning-rate measurements over the pressure range of 0.1–36 MPa were carried out in a constant-pressure windowed 1.5-L combustion bomb with a motion picture camera aimed at the burning pellets and single crystals. Within the pressure range of 1–10 MPa, a decrease in the strand cross-sectional size caused a decrease in the ADN burning rate, accompanied by a notable burning-rate data scatter. Within this pressure range, the burning

rate of strands with a diameter of 4 mm or less could differ by more than a factor of two. Small amounts of organic substances added to ADN appeared to suppress the scatter and strongly affected the burning rate. The burning-rate law $r_b = bp^n$ constants for recrystallized ADN pressed into plexiglass tubes 7 mm in diameter, covering all of the pressure range studied, is given in Table 22.

Table 22: Burning-rate law for pure ADN pressed into 7-mm plexiglass tubes.

Pressure interval, MPa	<i>b</i>	<i>n</i>
0.2–5.8	18.98	0.60
5.8–10	213.18	−0.80
10–36	9.06	0.60

$r_b = bp^n$ where r_b is the burning rate in mm/s
and p is the pressure in MPa.

Data source: [397]

In Figure 66, the $r_b = f(p)$ curve for pure ADN with its maximum and minimum of the burning rate is very similar to those reported earlier.

Figure 66: Effect of pressure on the mass burning rate of ADN pressed into 7-mm combustible plexiglass tubes with density of 1.79 g/cm³ (+) and 8.5-mm non-combustible quartz tubes with density of 1.54 g/cm³ (light points). (Reproduced and modified from [397].)

Surprisingly, a 90% supersaturated ADN solution in water can be ignited and sustains burning at 1 MPa at a rate less than the burning rate of neat solid ADN at this pressure. As the pressure increases, however, the burning rate of the solution rises very rapidly and has a maximum at 4 MPa, surpassing the neat ADN. As with ADN monocrystals, in this case the combustion instability area is distinguished very distinctly. However, the turbulent combustion of the supersaturated water solution reveals a local maximum on the burning rate versus the pressure curve in this area, whereas the crystals are incapable of sustained burning within the same pressure range.

Temperature profiles in combustion waves propagating into pressed ADN pellets were measured in the 0.04–10 MPa pressure range using thin tungsten-rhenium thermocouples [398]. The temperature profile data suggested that the ADN decomposition reaction in the condensed phase zone plays a dominant role in burning at low pressures. The heat feedback from the flame front to the surface appeared to be negligibly small. It was concluded that the reaction of AN dissociation to form NH_3 and HNO_3 controls the ADN burning surface temperature. The flame front of the ADN combustion wave consists of three zones, and theories explaining the main chemical reactions occurring in the three zones were proposed. One of the steps in the temperature profiles coincides with the dissociation temperature of AN, an intermediate in the ADN decomposition. The ADN surface temperature corresponds to the temperature of dissociation of AN, a decomposition product of ADN in the melt. Temperature just above the surface (the aerosol zone) is controlled first by the reaction of AN dissociation at the surface of small droplets, followed by dissociation of remaining ADN droplets tossed into the flame front. The first flame is due to NH_3 oxidation by nitric acid decomposition products. In the second flame, the complete thermodynamic heat release is attained. At low pressures (less than 1 MPa), the burning of ADN could be satisfactorily described by a condensed-phase combustion model with the rate-controlling reaction being the ADN decomposition in the melt. A gas-phase model with the rate-controlling reaction being HNO_3 decomposition in the first flame can be used to explain high pressures (greater than 10 MPa) burning. In the medium pressure interval (2–10 MPa), ADN showed combustion instabilities caused by a deficiency of heat produced in the condensed material. In this range, the fast but energy-limited heat-release process in the condensed phase has to adapt itself to the slow but energy-rich heat-release process in the gas phase. At 0.1 MPa, temperature measurements were carried out with molten ADN and paraffin-doped ADN (both capable of sustained burning at this pressure) and showed surface temperatures T_s for both materials in the range of 593–608 K.

Thermocouple studies showed that the lack of heat flux from the gas at least up to 4 MPa led to consideration of the condensed-phase chemistry as determining ADN combustion at low pressures [398]. It was proposed that it is AN formed in the decomposition of ADN in the melt, which dissociates from the ADN burning surface, thus controlling the surface temperature. Rate constants of the dominant combustion reaction of ADN in the pressure range of 0.02–1 MPa were obtained from Zel-

dovich's expression for the burning rate, taking the surface temperature, T_s , as the AN dissociation temperature. The average specific heat, c_p , was taken as $2.05 \text{ kJ kg}^{-1} \text{ K}^{-1}$ ($0.49 \text{ cal g}^{-1} \text{ K}^{-1}$); the thermal diffusivity of the condensed phase, χ , as $1.78 \times 10^{-7} \text{ m}^2 \text{ s}^{-1}$; heat of reaction, Q , as 1674 kJ/kg (400 cal/g); and heat of melting, H_m , as 14.2 kJ/mol (3.4 kcal/mol) [415].

As seen in Figure 67, the results derived from the combustion model,

$$k = 10^{16.37} \cdot \exp(-19630/T),$$

where k is the rate constant in s^{-1} and T is the temperature in kelvin, are in satisfactory agreement with ADN decomposition kinetics found by different ways, such as from dinitramide anion and ammonium cation disappearance rates [166],

$$k = 10^{16.94} \cdot \exp(-20080/T) \quad \text{and} \quad k = 10^{15.56} \cdot \exp(-19020/T)$$

and from rates of formation of gaseous decomposition products [241],

$$k = 10^{14.4} \cdot \exp(-17866/T) \quad \text{and} \quad k = 10^{15.4} \cdot \exp(-17765/T).$$

All of the data can be described fairly well in the temperature interval of 370–705 K by a general line, which is shown as a solid line in Figure 67.

$$k = 10^{16.16} \cdot \exp(-19375/T).$$

Figure 67 shows rate constants versus reciprocal temperature for the leading reaction of ADN combustion and the kinetics of ADN decomposition found from dinitramide anion and ammonium-cation disappearance rates, as well as from rates of formation of gaseous decomposition products. A solid line was then drawn through all the points. See also [416].

The thermal and combustion characteristics of ADN were measured by a pressure thermogravimetric analysis at pressures below 8 MPa [417]. The burning rates of pure ADN and ADN/AN mixtures were measured in the range of 0.2–12 MPa, and the burning temperature profiles were obtained using thermocouples with diameters of 5 and $25 \mu\text{m}$ in order to study the condensed-phase behavior in the vicinity of the burning surface as it progressed into the unburned material. Measurement of the temperature profiles was complicated because the ADN decomposition and AN dissociation competed in the condensed phase, and the bubbles of the decomposition gases and gas-phase flame also affected the surface temperature.

A study of the influence of various condensed-phase and gas-phase processes in determining the pressure and temperature sensitivities of the burning rate showed that ADN combustion is stable in the range of 0.5–2 MPa [318]. The pressure sensitivity of the burning rate has the form $r_b = 20.72p^{0.604} \text{ mm/s}$, and the burning characteristics are controlled by exothermic decomposition in the condensed phase. At 10–36 MPa, the burning rate can be correlated with pressure as $r_b = 8.50p^{0.608} \text{ mm/s}$. The pressure dependence of the burning rate, however, becomes irregular in the range of 2–10 MPa. This phenomenon may be attributed to the competing influence of the

Figure 67: Rate constants vs. reciprocal temperature for the leading reaction of ADN combustion. (Republished and modified from [415], with permission of © 2009 Elsevier Science & Technology Journals; permission conveyed through Copyright Clearance Center Inc.)

condensed-phase and gas-phase exothermic reactions in determining the propellant surface conditions and the associated burning rate.

4.11.1.2 Lower Pressure Limit of ADN Deflagration

The lower pressure limit of combustion of recrystallized ADN pressed into acrylic tubes 7 mm in diameter was found to be 0.2 MPa. The ability of pure ADN pellets to burn at atmospheric pressure has been disputed, and different interpretations have been offered for the disparate observations. An addition of an amount of paraffin as small as 0.2% to crystalline ADN extended the low-pressure limit of ADN-sustained combustion from 0.2 to 0.02 MPa (Figure 68; [418]).

In the subatmospheric pressure region (at 0.04 and 0.06 MPa), the temperature profiles for paraffin-doped ADN were typical of flameless combustion: a sharp temperature increase in the condensed zone followed by the gas zone of practically constant temperature, i.e., with practically zero temperature gradient above the burning surface [397, 398]. This temperature remained almost constant over all of the length studied (~6 mm) and was equal to 553–563 and 583–603 K at 0.04 and 0.06 MPa, respectively.

4.11.1.3 Effect of Initial Temperature on the Burning Rate

Burning-rate measurements at atmospheric pressure at different initial temperatures were conducted with samples of ADN pressed into plexiglass tubes 7 mm in diameter (Figure 69; [397]).

Although only a few experimental data points are available, the condensed-phase combustion model can be successfully used to describe combustion of ADN in a wide range of initial temperatures and at pressures less than 1 MPa. Figure 70 shows a comparison of experimental and calculated burning rates of ADN at different pressures and initial temperatures based on data from two different laboratories [402]. Note that in order to fit all five curves on one graph, four of the data sets were multiplied by an adjustment factor shown adjacent to the curves in the right-hand section of the graph. It can be seen that the burning rate coefficient (the slope of the curves) remained independent of temperature.

4.11.1.4 Computer Modeling of ADN Strand Burning

ADN not only has a very high burning rate, but it also has a very unique burning rate versus pressure behavior. This complex behavior is extremely difficult to model mathematically. An unstable region exists between 20 and 100 atm in the ADN monopropellant burning-rate curve. It has been attempted to develop computer models based on kinetic codes, computational fluid dynamics, and heat and mass transfer calculations to predict the strand burning rate of ADN by itself and eventually also the burning rates of actual solid propellants based on ADN as the oxidizer (Section 4.11.2.2). With the advances in computational chemistry, various aspects of ADN molecular structure, energy levels, decomposition, and burning have become accessible for theoretical studies, and the computer predictions have been compared to experimental results (not always with full success). It would be relatively easy to restrict the computations to the gas-phase burning, but mass and heat transfer in the boundary zone between the solid (molten) surface and the gas phase makes calculations more difficult. Similar calculations have been performed for other solid propellant oxidizers with and without the presence of a combustible binder.

A numerical method was developed to study the physical and chemical processes involved in ADN combustion [419, 420]. The analysis was based on the well-known conservation equations of mass, species concentration, and energy for both condensed and gas phases, and it considered finite-rate chemical kinetics and variable thermophysical properties. A chemical kinetics scheme, containing 33 species and more than 180 reactions, was established to investigate the gas-phase flame structure. The analysis was applied to ADN self-deflagration (in the absence of combustible binders) at 6 atm, with the measured surface composition used as the boundary condition. Results showed good agreement with experimental data in terms of the temperature and species concentration profiles in the gas-phase flame. Sublimation and dissociation of ADN to NH_3 , $\text{HN}(\text{NO}_2)_2$, N_2O , and HNO_3 are believed to be the major initial decomposition steps. However, surface conditions derived from these processes failed to accurately model the measured gas-phase flame structure if a different kinetics scheme was employed.

The theoretical burning-rate equation of ADN and its mixtures with various additives was derived based on the chemical structure [421]. The calculated values showed good agreement with experimental results. Based on the chemical structure and reaction, the mechanism of plateau combustion in pure ADN remains to be explained. The formation and disappearance of the intermediate product NH_4NO_3 play a key role in plateau or mesa combustion of ADN.

Data (species concentrations and temperature profiles) obtained from mass spectrometric analysis of the decomposition products of ADN can be applied to modeling the combustion of ADN in a flame, either ADN burning by itself or ADN burning in mixtures with solid propellant binders. Molecular-beam MS and thermocouple measurements were used to study ADN flame structures at pressures from 0.3 to 0.6 MPa [422, 423]. Based on these experimental studies and literature data, a general mecha-

nism for describing the chemical reactions in an ADN flame (including 172 reactions and 31 species) was developed and compared to data reported by earlier investigators, including [358]. The correlation between experimental and theoretical results was satisfactory. The scheme included a submechanism (98 reactions and 22 species) for propellant combustion suggested by Yetter and Dryer. The latter was further supplemented by a set of 74 reactions, including 63 steps suggested by Lin and Park and the ADN dissociation reactions suggested by Korobeinichev, Bolshova, and Paletsky [423]. The correlation between the experimental and calculation results was satisfactory.

The book on thermal decomposition and combustion of explosives and propellants by Manelis et al. [424] contains chapters devoted to strand burning of individual oxidizers such as AP, AN, and ADN, as well as a more general chapter on developing a model that can be applied to all of those oxidizers that decompose in the condensed phase [424]. That chapter describes the different modes of reactions in the condensed phase of burning pure substances, dealing mostly with solid propellant oxidizers such as AP, AN, and ADN. The models describe different paths, depending on whether the substance burns with dispersion of the condensed phase (spattering, geysering), foaming, or a combination of condensed-phase reaction and evaporation or sublimation. These models are then applied to the study of strand burning of AP, HAP, AN, HN, hydrazinium(1+) chloride, and ADN. It was concluded that for ADN and a few other onium salts, the exothermic decomposition in the condensed phase and evaporation are the determining factors in determining the surface temperature and the regression rate. Dispersion (particle ejection, spattering, or foaming) plays only a secondary role. Gas-phase reactions contribute to the decomposition energy release only at high pressures. It is estimated that in the case of ADN decomposition, the contribution of gas-phase reactions is only 3% of the overall energy release.

Subsequent to and based on a thorough review of the ADN decomposition literature through 2006, a multi-phase model for the combustion of ADN in the absence of fuel additives has been developed using the BYU PHASE3 combustion code [425]. The model uses a single, global condensed-phase reaction and assumes that ADN evaporates to form the molecular complex $(\text{ADN})_{\text{associated}}$. The proposed mechanism is a parallel decomposition path in which ADN is converted to AN via one path and ADN is converted to NH_3 and dinitramidic acid by way of a second, competing path. The proposed condensed-phase decomposition reaction schematic is illustrated in Figure 71.

Very good results were obtained using a single, global condensed-phase reaction for the first segment of the burning rate curve. The model accurately predicted burning rates, temperature and species profiles, and other combustion characteristics of ADN at pressures below the unstable region ($2\text{--}10\text{ MPa} = 20\text{--}100\text{ atm}$) of combustion. Burning rates were also predicted halfway accurately in the unstable pressure regime and at higher pressures. The decomposition of AN must be included when designing an ADN combustion model because ADN is converted to AN in the first stage. The majority of AN is assumed to decompose in the condensed phase.

Figure 71: Proposed condensed-phase ADN decomposition pathway. (Adapted from [425].)

In order to verify the adequacy of various models of heat release in ADN flames proposed by other authors and to compare the results to real-world processes, the chemical processes in products of thermal decomposition at a pressure of 10 mm Hg and in ADN flames at pressures from 0.04 to 6.06 MPa (0.4–60 atm) were numerically simulated [426]. The calculations were performed on the basis of a detailed kinetic mechanism, and the boundary conditions were correlated with experimental data, thermodynamic properties, and initial chemical composition of ADN. The kinetic mechanism included sub-mechanisms that describe high-temperature chemical processes in $\text{N}_2\text{O}/\text{NO}/\text{NO}_2/\text{HNO}_2/\text{HNO}_3/\text{NH}_3$ and $\text{NH}_3/\text{HN}(\text{NO}_2)_2$ mixtures and the global stages of aerosol decomposition. Based on calculated and experimental data, the roles of dinitraminic acid $\text{HN}(\text{NO}_2)_2$, AN aerosols, ADN aerosols, and ADN vapor in heat release in the ADN flame zone adjacent to the burning surface were examined. The calculations predicted that the main source of heat release in the cold flame zone at $p \geq 3$ atm would be dinitraminic acid, which is formed by dissociative evaporation

from the burning surface. In the second high-temperature flame zone, heat release is caused by reactions that occur in the $\text{N}_2\text{O}/\text{NO}/\text{NO}_2/\text{HNO}_2/\text{HNO}_3/\text{NH}_3$ mixture. At moderate pressures, the high-temperature and low-temperature zones are separated by an induction zone. The stage that governs production of the OH radical, which plays an important role in combustion of ADN, is the reaction

Because of the high activation energy of this stage, small temperature perturbations in the induction zone at low pressures lead to a finite change in the stand-off distance between the high-temperature flame zone and the burning surface. Therefore, small temperature perturbations in the induction zone, which are caused by admixtures in the sample or by heat transfer between the reacting gas and the ambient medium, may be responsible for disagreement between various experimental data and between experimental and calculated data of the stand-off distance between the high-temperature flame zone and the burning surface. This can be measured by high-speed cameras through the windows of a combustion bomb.

A numerical calculation model with a coupled condensed-phase/gas-phase kinetics mechanism was developed to study the physical and chemical processes involved in ADN combustion and to predict the characteristics of combustion waves [427–429]. The model was based on the conservation equations of mass, species concentration, and energy for both the condensed phase and the gas phase, and it takes into account finite-rate chemical kinetics and real thermophysical properties. Finally, an equation of state for a multicomponent system was employed to connect the equations. A chemical kinetics scheme, containing 34 species, one condensed-phase global ADN decomposition reaction, and 165 detailed reactions in the gas phase, was established and employed in the model. The gas-phase mechanism model was applied to predict species mole-fraction profiles and temperature profiles in ADN gas-phase flames at 0.6 MPa. The coupled condensed-phase/gas-phase mechanism was employed to predict ADN strand burning rates and burning surface temperatures at pressures from 0.2 to 36 MPa. The agreement between calculation results and experimental data was satisfactory. The results indicated that the coupled condensed-phase/gas-phase kinetics mechanism can predict ADN combustion with reasonable accuracy. See also [430].

The surface temperature in the combustion wave of ADN, as well as in AN, HNF, and AP, is controlled by a dissociation process similar to that postulated for other onium salts [431].

A comprehensive multi-phase combustion model describing the physiochemical processes involved in the autodecomposition combustion of ADN was based on the conservation equations of mass, species concentration, and energy, and it took into account finite-rate chemical kinetics in both the condensed and gas phases [432]. Based on an extensive review of the literature on ADN thermal decomposition, three global decomposition reactions in the condensed phase of ADN were selected. A detailed chemical kinetics scheme involving 34 species and 165 reactions was employed to describe the gas phase. Detailed combustion-wave structures and burning-rate characteristics of ADN can be described by this model. The optimized gas-phase kinetics mechanism was able to predict the multi-stage flame structure of ADN self-deflagration flames. Good agreement between the predicted and measured profiles of temperature and species mol fractions was obtained at different pressures, and moderate agreement between calculated and measured values of

propellant burning rates and surface temperatures was obtained over a broad range of pressures from 70 kPa to 3.53 MPa (0.7–350 atm). The burning rate increased with pressure, except in the middle range of ~6.06–10.1 MPa (~60–100 atm). The coupled condensed-phase/gas-phase analysis employed in the current model was able to capture this irregular/unstable combustion behavior in the middle range, where the burning rate decreased with the increase in pressure, which is quite unusual.

4.11.1.5 Strand Burning of ADN Solutions

ADN solutions in water or formamide ignited in glass tubes 4–6 mm in diameter display a transition from laminar to turbulent burning initiated by a steep rise in the burning rate [396, 433]. At pressures greater than 15 MPa, this turbulent burning regime seems to undergo a transition to another more stable combustion regime marked by a weak dependence of the burning rate on pressure, as well as smooth burning of the entire charge for the entire length of the sample holder tube. In this range, most additives decrease the burning rate. An aqueous solution containing 75% ADN burned with a regression rate of 4 mm/s at 4 MPa [395].

4.11.2 Ammonium Dinitramide Combustion in Solid Propellants

Several sections in this chapter have already dealt with the thermal decomposition and combustion of pressed ADN pellets in the absence of a combustible binder. There is some inevitable overlap between those sections and other works studying the combustion of ADN in the presence of a combustible binder. We are trying to avoid repetition, but several publications are referenced in both locations, here and elsewhere. The papers discussed in the following sections deal with experimental as well as theoretical-computational studies of ADN as the oxidizer in the combustion of fuels in solid propellants. Sometimes the only combustible material in contact with ADN is the straw or thin tubing into which the oxidizer has been tamped or pressed to form the shape of a long cylinder for strand burning tests. Quite often the straw is polymethylmethacrylate, which has good see-through characteristics for high-speed photography in a windowed combustion bomb.

4.11.2.1 Experimental Study of ADN Combustion in Model Solid Propellants

Quite often the oxidizer/fuel combinations used for academic combustion studies do not meet all of the mechanical and structural requirements for a good propellant. These are only models for the real thing, but they are easier to deal with.

Sometimes a combustible non-polymeric substance is dry-mixed with the oxidizer and pressed into pellets for burning-rate studies. This is done because it is much easier to dry-mix the ingredients than to mess around with sticky pre-polymers and wait for several days until a formulation has cured. Pressing the samples into pellets in a hydraulic press is much faster and allows more variables. Particle size must be controlled, though.

In contrast to AP, an addition of any fuel to ADN did not appear to increase the burning rate. This is an unlikely result, but a 1000 °C increase in the flame temperature upon addition of the fuel did not cause the burning rate to increase. Moreover, the burning rate of the oxygen-balanced mixture with 7% of paraffin is actually less than that of neat ADN.

Several types of instruments based on microprobe and molecular beam mass spectrometric sampling have been developed and applied to ADN, AP, and double-base propellant combustion as examples [434]. TOF mass spectrometers connected to a skimming inlet can study combustion at high (>10 atm) or low (<1 atm) pressures.

The effect of fuels on the burning rate of ADN was studied by varying the O:F stoichiometric ratio and the pressure [395]. The fuels tested included anthracene, phenantrene, succinic acid, phthalic acid, hydroquinone, resorcinol, diphenylamine, hexamethylenetetramine, dinitrobenzene, dinitrophenol, and RDX. All fuels, with the exception of oxamide, had a similar effect on the burning rate of ADN. Minor amounts (0.5–1%) of fuel additives actually decreased the burning rate of ADN, particularly in the area where pure ADN had a maximum in its burning rate curve. Mixtures with oxamide burned the slowest, and mixtures with dinitrophenol burned the quickest.

When a burning pressed ADN pellet is surrounded by a combustible environment, this has practically no effect on the burning rate of pressed strands [433]. However, when the organic material is intimately mixed with the ADN before pressing it, this will allow ADN to burn even at very low pressures. In the pressure range from 2 to 20 MPa, a decrease in the strand diameter will cause a decrease in ADN burning rate, and the data are plagued by more data scatter. ADN single crystals (as opposed to pressed strands) did not burn at all at these pressures. The reason for this burning behavior is assumed to be a dominant role of condensed-phase decomposition reactions taking place in burning ADN. The ADN surface temperature is controlled by dissociation reactions, which are dependent of pressure. Since the amount of heat that can be released in the condensed phase is limited, combustion of ADN occurs on the verge of condensed-phase energy levels. Because ADN has such a low melting point and the surface layer is liquid, burning is accompanied by significant spattering of the melt layer that consists of ADN and some AN (the first decomposition product). Entrainment of condensed-phase droplets into the gas zone reaches its maximum in the pressure regime of unstable combustion (2–10 MPa), resulting in more scatter of burning-rate data. However, at the lower pressure limit of ADN deflagration, where the fraction of ADN ejected into the gas phase is larger, the dispersion retards the burning process because the energy release is scattered over a wider area. If the surface tension of the polar melt is reduced by the addition of organic compounds, the lower pressure limit of deflagration is lowered, and there is less data scatter.

The strand combustion of pure ADN suffers from combustion instability in the pressure range of 2–10 MPa. However, even small amounts of organic additives (<1%) result in a reduction of both burning rates and their scatter in this pressure range. Polycaprolactone (PCL) is not the best binder for solid rocket propellants, but it burns

cleanly and can be used in academic settings where the use of isocyanates and more toxic curing agents must be avoided. Combustion studies of ADN with PCL showed that PCL inhibits the reactions of ADN decomposition in the condensed phase [435, 436]. This leads to a decrease in the burning rate. The ADN used in this study contained 2% of AN as an impurity. It was shown that the particle size of the oxidizer influences the burning rate of ADN/PCL. The pressure exponent for propellant with bimodal oxidizer decreased to 0.72 in comparison with propellant on a base of fine oxidizer within a pressure range of 3–8 MPa. Burning rates of the 98% ADN/2% CuO mixture at pressures of 4–8 MPa were compared with those for pure ADN; the burning rates of this mixture were in a straight line beneath the lower boundary of the burning rates of pure ADN, which were scattered all over the graph grid. CuO catalyst increased the rate of reactions and heat release in the condensed phase and in the gas phase near the burning surface.

Sandwich combustion of laminated layers of oxidizers and fuels is one of the many methods to study and model heterogeneous solid propellant combustion. In some of these experiments, the deflagration of the oxidizer (AP or ADN) by itself (without addition of a fuel lamina) was examined as the baseline [437].

In addition to measuring burning rates and combustion temperatures, it is also of interest to analyze exhaust gases and to compare the results with theoretical predictions. Again, the ADN/PCL combination was used as the model propellant to demonstrate the operation of a new exhaust-gas sampling system. A new probe method for determining the quantitative composition of solid-propellant combustion products at temperatures of 2500–3200 K and pressures of 4–8 MPa under conditions typical of rocket motor conditions allows a sample to be frozen without passing through the main shocks inside the sampler and to be saved for later analysis [438]. See also [439].

4.11.2.2 Computer Modeling of ADN Combustion in Solid Propellants

This section is an expansion and continuation of Section 4.11.1.4, with the addition of combustible substances. With the advances in computational chemistry, various aspects of ADN molecular structure, energy levels, decomposition, and burning have become accessible for theoretical studies, and the computer predictions have been compared to experimental results (not always with full success). It would be relatively easy to restrict the computations to the gas-phase burning, but mass and heat transfer in the boundary zone between the solid (molten) surface and the gas phase makes calculations more difficult. Similar calculations have been performed for other solid propellant oxidizers with and without the presence of a combustible binder.

The combustion process of ADN has been modeled in two different situations: decomposition in an open environment, with a flow of abundant air transporting the products, and decomposition in rocket-motor internal environmental conditions surrounded by the decomposition products [440]. The rate of combustion and concentration of species in the open-air environment were higher than those in the rocket-motor environment, showing the effect of the different atmosphere in the reactions kinetics.

4.11.3 Burning-Rate Catalysts for Ammonium Dinitramide Combustion in Solid Propellants

Future volumes in this series may contain the general discussion of the effect of additives on the strand burning rates of pressed oxidizer pellets or formulated solid propellants. The current section deals specifically only with ADN in the absence of combustible binders. Many of the additives tested here are the same that have historically been used for AP-based solid propellants with moderate success. The burning rates of pressed pellets of ADN are much higher than those of AP; therefore, burning-rate catalysts are rarely needed.

4.11.3.1 Metals as Burning-Rate Catalysts for ADN

Metals can affect the burning rates of solid propellants only if they are finely divided. This is where the new nanometal powders are finding new applications.

4.11.3.2 Metal Oxides as Burning-Rate Catalysts for ADN

Finely divided nano-size iron(III) is a very effective burning-rate catalyst for all types of solid propellants. A nanocomposite iron(III) oxide freshly hydrolyzed and precipitated on ADN is a high-performance, high-burning-rate oxidizer [441]. By using 1,2-epoxypropane (propylene oxide) as the agent for controlling the rate of hydrolyzation of Fe^{3+} ions, an ADN/ Fe_2O_3 composite wet gel was prepared by a sol-gel method under mild conditions. An ADN/ Fe_2O_3 aerogel was obtained by means of supercritical CO_2 fluid dehydration. Transmission electron microscopy

Figure 72: Effect of additives on burning rate of pressed ADN pellets. (Reprinted and modified from [443]. This image is in public domain.)

(TEM), scanning electron microscopy (SEM), energy-dispersive X-ray spectroscopy (EDS), IR, DSC, and sensitivity tests were employed to characterize the appearance, structure, thermal behavior, and mechanical sensitivity of the samples. The results indicated that the as-prepared ADN/ Fe_2O_3 nanoparticles are about 50–100 nm in diameter and are much less sensitive to mechanical stimuli. Moreover, the ADN/ Fe_2O_3 nanoparticles decompose at a lower temperature with the disappearance of the melting endothermic peak.

Micrometer-sized particles of Al, Fe_2O_3 , TiO_2 , NiO, $\text{Cu}(\text{OH})\text{NO}_3$, Cu, and CuO, and nano-meter-sized Al (Alex) and CuO (nanoCuO) were employed as the additives for pelletized ADN in the absence of binders [442] and with added binders [443]. The burning rates of pelletized ADN were measured at pressures ranging from 0.6 to 6.2 MPa. Nanosized CuO enhanced the burning rate of pelletized ADN, but only below 3 MPa. Alex-incorporated ADN burned with flames even at 0.55 MPa, under which pure ADN does not support combustion by itself. Figure 72 illustrates the effects of additives on the strand burning rate of pelletized ADN. The burning rates of most of the other samples with additives were lower than those of pure ADN pellets under those conditions.

4.11.3.3 Metal Carbonates as Burning-Rate Catalysts for ADN

The effect of lead(II) carbonate (PbCO_3) on the combustion characteristics and thermal decomposition behavior of ADN was investigated using burning-rate measurements, DSC, and TGA [444]. Results showed that the burning rate of an ADN + 5% PbCO_3 + 0.2% paraffin system is higher than that of an ADN + 0.2% paraffin system in the pressure range of 3–12 MPa, and PbCO_3 causes the mesa combustion effect in the ADN + 0.2% paraffin system to disappear. TGA and DSC curves of ADN and ADN + 5% PbCO_3 indicated that the onset of decomposition temperature of ADN can be decreased by the addition of PbCO_3 . Kinetic analysis for DSC data showed that the apparent activation energy of thermal decomposition of ADN decreased when 5% PbCO_3 was added into ADN.

4.11.3.4 Metal Complexes as Burning-Rate Catalysts for ADN

The effect of organometallic compounds on the combustion and thermal decomposition of ADN was investigated using burning-rate measurements, DSC, and TGA [445]. It was shown that organometallic compounds can increase the burning rate of ADN within the pressure range of 1–12 MPa. TGA and DSC tests for ADN and ADN+1% organometallic compounds indicated that the initial decomposition temperature of ADN can be noticeably decreased. The initial onset of decomposition temperature of ADN is dependent on the number of organometallic compounds added. Kinetic analysis of DSC and TG data showed that the activation energy of thermal decomposition of ADN was decreased by about 30% by the addition of only 1% of organometallic compounds to ADN.

4.11.3.5 Nanomaterials as Burning-Rate Catalysts for ADN

Bismuth oxide is rarely used as a burning-rate catalyst for any rocket propellant, and even less so for ADN. Nevertheless, the catalytic activity of bismuth oxide deposited on carbon nanotubes (CNTs) has been tested. CNTs supporting bismuth oxide (Bi_2O_3) nanometer particles were prepared by a microwave radiation method and characterized by means of SEM, X-ray photoelectric spectroscopy, and XRD [446]. The catalytic activity of Bi_2O_3 nanometer particles on the thermal decomposition of ADN was investigated by TG and DSC. The results showed that nanometer Bi_2O_3 was coated uniformly on the surface of the nanotubes.

The catalytic activity of CNTs, CNTs supporting ferric oxide ($\text{Fe}_2\text{O}_3/\text{CNT}$), and CNTs supporting iron and copper ($\text{Fe}\bullet\text{Cu}/\text{CNT}$) for the combustion and thermal decomposition of ADN were investigated through burning-rate measurements and TGA [447, 448]. Results showed that all three catalysts increased the burning rate of ADN. The burning rates were related to combustion pressure by an exponential burning-rate function, and the pressure exponents decreased with the amount of catalyst for all of the three catalysts. When 3 mass-% of catalyst was used, the burning rate of ADN at 4 MPa increased from 30 to 50 mm/s, 40, and 39 mm/s and the pressure exponents decreased from 0.81 to 0.36, 0.67, and 0.75 for the CNTs, $\text{Fe}_2\text{O}_3/\text{CNTs}$, and $\text{Fe}\bullet\text{Cu}/\text{CNTs}$, respectively. TGA tests showed that all three catalysts decreased the onset of thermal decomposition temperature of ADN. When 1 mass-% catalyst was added to the ADN, the thermal decomposition onset temperatures of ADN decreased by 18.3, 12.1, and 11.6 °C for the CNTs, $\text{Fe}_2\text{O}_3/\text{CNTs}$, and $\text{Fe}\bullet\text{Cu}/\text{CNTs}$, respectively.

4.11.4 Burning-Rate Studies with Alkylammonium Dinitramide Salts

A large number of dinitramide salts of organic amines were synthesized, and their physical properties and strand burn rates were measured [412, 449]. It was attempted to obtain a correlation between the basicity constant of the amine and the burning rate of its dinitramide salt, but not all data fit into the same scheme. The burning rates of the dinitramide salts of various aliphatic, aromatic, and heterocyclic amines were compared to the corresponding perchlorates. The advantages due to the ability of dinitramides to burn at lower pressures and over a wider pressure range disappear at higher combustion pressures.

5 Toxicity of Ammonium Dinitramide

As soon as ADN became available, several studies were performed by the U.S. Air Force Toxicology Division to evaluate the toxicity of this new chemical [450, 451]. These studies included acute and subacute toxicity screening, a 90-d reproductive screen and three follow-on reproductive studies, electron paramagnetic resonance (EPR) spectroscopy studies, mutagenicity assays, and a study evaluating the effects of ADN on hepatocytes *in vitro*. The results of the *in vivo* studies indicated that ADN is a female

reproductive toxicant in rats, causing implantation failure during early gestation. The follow-on studies implied that ADN is even embryotoxic. EPR studies indicated that ADN can decompose to form reactive nitrogen metabolites that can be harmful in biological systems. The hepatocyte studies suggested that ADN has the potential for directly affecting cellular DNA *in vitro*. Additional traditional genotoxicity assays indicated that ADN is potentially mutagenic.

Eurengo Bofors started analyzing environmental and toxicological effects of ADN and GUDN (also called FOX-12) [452]. The tests were performed by independent and accredited test institutes (Research and Consulting Company, Itingen, Switzerland), and they are in full accordance with the requirements in the European Registration, Evaluation and Authorisation of Chemicals (REACH) regulations. The products have been registered and have all received ELINCS-numbers (i.e., they are on the European List of Notified Chemical Substances according to REACH). ADN is registered according to REACH and has received the ELINCS-number 453-090-2. The results of the tests are shown in Table 23.

Table 23: Results of toxicity and environmental screening of ADN.

Type of test	Results
Toxicity LD50 (oral rat)	832 mg/L
Toxicity to aquatic organisms EC50	> 10000 mg/L (15 min)
Acute inhalation	May cause irritation
Sensitizing	Not sensitizing
Effect on skin	Not irritating
Effect on eyes	Not irritating
Lipophilicity	$\log P_{o/w} < -2.8$
Mutagenicity mammalian cell	Negative
Biodegradability COD	0.2 g/g
BOD7/COD	0.5

Data source: Stenmark and Sjoekvist [452]

According to these tests, ADN is considered to be non-carcinogenic and non-allergenic. It is not irritating when in contact with skin or eyes but may cause irritation if inhaled. ADN is harmful if swallowed.

5.1 Oral Toxicity of Ammonium Dinitramide

Because the most significant exposure route expected for ADN would be accidental ingestion, acute oral toxicity animal tests were conducted [453]. In preparation for a reproductive screen on ADN, stability and palatability studies were also conducted. Oral administration of ADN at 5 g/kg body weight (the U.S. Environmental Protection

Agency [EPA] limit dose) produced convulsions and rapid death in all treated rats. Subsequent studies indicated an acute LD₅₀ in F-344 rats of 823 mg/kg. Administration of either 12, 25, 50, or 100 mg ADN/mL of drinking water on a continuous basis for 2 weeks to male and female Sprague-Dawley rats produced no apparent effect on body weight gain, water consumption, organ weights, hemoglobin concentration, or methemoglobin formation. Dermal application of 2 g/kg (EPA limit dose) produced no toxic signs in rabbits.

It was hypothesized that ADN decomposes in the body to form free radicals that would then destroy living cells. This hypothesis was tested on liver cells *in vitro* [454]. Liver cells were chosen because, regardless of the mode of administration, ADN will enter the bloodstream and ultimately pass through the liver. Leakage of the enzymes aminotransferase, alanine aminotransferase, and lactate dehydrogenase was taken as an indication of cell damage in WB344 hepatocytes after a 24-h exposure to ADN. Incubation of hepatocytes with 2.8 mM of ADN solutions for 24 h was toxic to 50% of the cells. Cells exposed to ADN produced free radicals that could be trapped chemically by two free-radical scavengers ("spin traps") and sensed by EPR, but not in all of the tests. EPR can detect free radicals in concentrations down to 10^{-10} M. Three of the four tests showed that increasing the ADN concentration will cause reduced cell viability.

In an evaluation of acute and subacute toxicity of ADN, oral gavage of ADN solutions greater than 1 g/kg resulted in mortality preceded by convulsions for male rats [455]. An oral LD₅₀ of 823 mg/kg was determined for male Fischer 344 rats. Rats receiving non-lethal doses of ADN showed no treatment-related effects when necropsied following a 14-d observation period.

In studies to try to determine a mechanism of action of ADN in biological systems, the interaction of ADN and its decomposition reaction intermediates on deoxyribose nucleic acid (DNA) was analyzed *in vitro* [456]. Some of the intermediates of ADN decomposition are free radicals. Free radicals can alter the genetic code in living cell propagation and induce cancer. EPR spectroscopy was used to determine whether radiation induces chemical changes in ADN by formation of free radicals. Irradiated ADN powder generated two superimposed EPR spectra, which were tentatively identified as NO₂ and NH₃ radicals. An electron nuclear double resonance (ENDOR) method was then used to verify the EPR results. The initial results of these experiments suggested a proton interaction proximal to the NH₃ radical center. Both reactive oxygen metabolites (ROMs) and reactive nitrogen metabolites (RNMs) play an important role in normal physiology and pathophysiology in biological systems. In order to identify the free radicals, they were made to react with a spin-trapping agent (*N-tert*-butyl- α -phenylnitron [BPN], 10-mM solution) that, in the presence of ADN, yielded overlapping spin adduct EPR spectra [457]. Precision-cut human liver slices were incubated in the presence of BPN with and without 10 mM ADN solutions. The liver slices were then homogenized, frozen in liquid nitrogen, and lyophilized. ADN oxidized the BPN

in human liver within 5 min of exposure to form a yellow compound that was no longer paramagnetic. The reaction of ADN with liver caused acute injury.

High-pressure liquid chromatography studies revealed the formation of ADN-fragmented DNA [458, 459]. Damage to DNA in solution was caused by at least two major pathways, one arising from reactions of NO_2 with oxygen and the other arising from a reaction with superoxide (O_2^-). The radical species generated when ADN was incubated with standard solutions of DNA, pH 7.5, in the presence of the spin-trap agent BPN was compared to the BPN-radical adducts generated in the presence of ADN and O_2^- or of ADN and H_2O_2 . The synergistic effect of ADN with O_2^- may provide an understanding of the sensitivity of rat blastocysts to ADN at the preimplantation stage of development and the lack of toxicity in *in vivo* studies in tissues that are high in catalase.

5.2 Cutaneous Toxicity of Ammonium Dinitramide

Preliminary field reports from exposed personnel have indicated that the chemical is readily absorbed into the skin, resulting in numbness of the fingers. Because the most significant exposure route expected for ADN would be dermal exposure, acute dermal toxicity tests were conducted [453, 455]. Dermal toxicity in New Zealand white rabbits, performed at the EPA's limit dose level of 2 g/kg body weight, resulted in no mortality and no clinical signs or differences in clinical pathology following a 14-d post-treatment observation period.

5.3 Mutagenicity of Ammonium Dinitramide

ADN was examined for its genetic toxicology effects using a combination of short-term mutagenicity screening assays, which included Salmonella/microsome mutagenesis (Ames test), mouse lymphoma cell mutagenesis (L5178Y-TK test), and an *in vivo* mouse bone marrow micronuclei assay [460, 461]. Results of Ames testing indicated that ADN is a base-pair substitution mutagen, causing about twofold (without S9) or threefold (with S9) increases of revertants in TA100, while there was zero increase of mutants in TA1535, TA1537, and TA98. ADN also induced mutation at the TK locus of mouse lymphoma cells, causing 40–95% (without S9) or 130–220% (with S9) increases of mutants. The *in vivo* micronuclei examination revealed a dose-dependent increase of micronucleated cells in the bone marrow of both male and female mice treated with ADN in a dose range of 62.5–750 mg/kg (single dose for 3 consecutive days), with a maximal induction of threefold increase at the highest dose. These tests demonstrated that ADN is mutagenic to both bacteria and mammalian cells and causes chromosomal damage in mouse bone marrow cells *in vivo*.

5.4 Carcinogenicity and Genotoxicity of Ammonium Dinitramide

In vitro toxicity, stress gene induction, and genotoxicity of ADN were determined as part of the initial phase of toxicity testing and evaluation of ADN [462]. First, the liver enzymes alanine aminotransferase (ALT) and aspartate aminotransferase (AST) were measured to estimate the membrane integrity of WB 344 hepatocytes. It was found that ADN increased leakage of both of these enzymes at all concentrations studied. Normalized EC_{50} s were determined at percentage of controls: ALT $EC_{50} = 2.7$ mM and AST $EC_{50} = 3.2$ mM. Next, to measure interactions of ADN with cellular regulatory transcription factors, genetically engineered human cell lines with fused human and bacterial stress-inducible genes were observed for the stress gene induction followed by *in vitro* ADN treatment. The stress reporter gene induction profile reflected that ADN induced the promoted sequences for all genes observed in the assay. Finally, preliminary assays to determine genotoxicity/mutagenicity of ADN were performed. These studies measured damage caused by DNA to living cells, potentially giving rise to mutations and subsequent tumors, and indicated that ADN has the potential for directly affecting cellular DNA. The results of the yeast recombination assay indicated that ADN may be a genotoxin but possibly not a direct-acting genotoxin. The assay uses two criteria: survival of the yeast cells and the recombination frequency. ADN may act through an oxidative challenge that may directly or indirectly damage nuclear DNA.

5.5 Teratogenicity and Reproductive Toxicity of Ammonium Dinitramide

Initial studies had shown that ADN is a female reproductive toxicant, causing implantation failure in Sprague-Dawley rats when it was administered during the preimplantation period of gestation. Male and female rats received drinking water containing 0.0, 0.2, 1.0, or 2.0 g ADN/L throughout the study. Mating occurred following 14 d of treatment. [463, 464].

The potential of ADN to produce alterations in paternal fertility, maternal pregnancy and lactation, and growth and development of offspring was studied in male and female rats that received drinking water treated with 200, 100, or 20 mg ADN/100 mL throughout the study [465]. Mating occurred following 14 d of treatment. All dams, one-half of the males, and representative pups were maintained for a total of 90 d of treatment. No mortality occurred in parental animals during the study. Adverse treatment-related decreases were noted in the maternal and paternal fertility indices, gestational indices, and live birth indices of the high-dose and mid-dose groups. Litter sizes in the high-dose and mid-dose groups were significantly smaller than those of the low-dose and control groups. Gross and histopathologic examination of the animals failed to identify the cause for the decrease in litter production in the high-dose and mid-dose dams. This study indicated that ADN is a reproductive toxicant. The no observable effect level (NOEL) was 29 mg/kg/day, the median dose of the low-level female rats.

In a study of preimplantation effects of ADN administered in the drinking water of Sprague-Dawley rats, in phase I, mated female rats were treated with 2 g/L ADN in their drinking water for 24, 48, 72, or 96 h before preimplantation embryos were harvested from the oviducts or uterine horns [466, 467]. In phase II, 2-cell embryos were harvested from the oviducts of superovulated mated B6C3F1 mice. The embryos were cultured for 72 h in medium supplemented with 0, 1, 4, 6, 10, or 20 mM ADN. The development of embryos cultured at <4 mM ADN was not affected compared to the control group. Culture in medium containing >4 mM ADN either slowed or arrested development of the embryos. These data suggest that the implantation failure seen in animals treated with ADN was due to embryo lethality.

A 90-d general toxicity/reproductive screen performed with ADN in rats at doses of 162, 103, 29, and 0.0 mg ADN kg⁻¹ d⁻¹ resulted in a distinct treatment-related adverse effect on litter production [468, 469]. Incidences of animals producing litters increased (1/11, 3/12, 12/12, and 11/12, respectively), and the mean number of pups per litter increased (7, 7, 16, and 15, respectively), both statistically significant differences. In a follow-up study, mated dams treated with ADN at the same doses and examined at gestation days 10 and 20 showed a similar effect in fetus loss as those in the reproductive screen. A pre-implantation versus post-implantation dosing regimen indicated that implantation is vulnerable to ADN effects during the pre-implantation period (gestation days 1–3). The pituitary gland was not specifically identified as a site of primary action, but serum progesterone was reduced by 27%, which may have resulted in reduced fertility.

The purpose of a follow-up study was to identify the mechanism(s) associated with implantation failure following exposure to ADN [470]. Mated female rats were treated with 2.0 g/L ADN in their drinking water for 24, 48, 72, or 96 h before preimplantation embryos were harvested from the oviducts or uterine horns. On gestation day 1 (GD-1), comparable numbers of morphologically normal two-cell embryos were harvested from the oviducts of the treatment and control groups. On GD-2, the development of the embryos harvested from the treated animals was either slowed or halted compared to the control embryos. By GD-4, 98% of the embryos harvested from the control group had developed to the morula or blastocyst stage; these were collected from the uterine horns. On GD-4 in the treated group, 41% of the harvested embryos remained at the two-cell to six-cell stage, and 59% were degenerate; 82% of these embryos were collected from the oviducts. These data suggest that the implantation failure seen in animals treated with ADN is due to embryo lethality.

A follow-up pre-implantation study indicated that ADN exerts its effects during the preimplantation period in rats during gestation days 1–3. The number of corpora lutea was consistent in each group, indicating that ovarian function was not affected by ADN treatment. Serum progesterone, prolactin, and estradiol were affected by ADN treatment compared to the control group. These hormone levels were also driven by maternal signals and normal implantation/embryonic development, so these data are somewhat ambiguous. The cause of implantation failure could occur at a number of

other points during the reproductive process: 1) oviduct mobility, which affects sperm, ova, and embryo transport, 2) uterine receptivity, or 3) ova/embryo lethality.

5.6 Aquatic Toxicity of Ammonium Dinitramide

Because ADN is intended as a replacement for AP, which turned out to be very persistent once it entered the groundwater and aquifers, the authorities made an extra effort to make sure that the AP replacement was not plagued by the same environmental problems as the oxidizer it was intended to replace. Thus, the aquatic toxicity of ADN and its photolysis products were tested under laboratory and field conditions.

The *Hydra attenuata* assay exposes both adult hydra and “artificial embryos” composed of disassociated hydra cells to test compounds to investigate developmental toxicity. Results from the hydra assay of ADN indicated that the minimal effective concentrations required to elicit a toxic response in the adult hydra and in the regenerating hydra were 750 mg ADN/L in both cases [471]. The developmental hazard index (A/D ratio) of 2.14 determined for ADN showed that ADN should not be considered a primary developmental toxin in the context of this assay.

In addition to ADN, the aquatic toxicity of *N*-GUDN, or FOX-12, was tested under the same conditions in the water flea, *Daphnia magna* [472]. The calculated acute toxicity (EC_{50}) value of ADN in the water flea was 405 mg/L after 48 h of exposure. With reference to the concentration of ammonium in the water, ADN is equally acutely toxic to *D. magna* as ammonium chloride. The solubility of FOX-12 in water is very low. A saturated solution of FOX-12 was not acutely toxic to the water flea. Additional work compared the aquatic toxicity of ADN and FOX-12 and their photolysis products to that of CL-20 and FOX-7 and used a different water flea (*Ceriodaphnia dubia*) as the test species [473]. The highest concentration tested (83 mg/L) of FOX-7 was not acutely toxic on its own or in combination with UV-A. The 48-h EC_{50} values for CL-20, FOX-12, and ADN were 6.4, 61, and 463 mg/L, respectively. In combination with UV-A, the toxicity was significantly enhanced for these three explosives.

5.7 Toxicity of Ammonium Dinitramide to Soil Bacteria

Cultured tests of bacteria in media amended with ADN indicated that dinitramide is not used by aerobic bacteria (*Pseudomonas*) as a sole source of nitrogen [474]. Similar results were obtained with pure cultures of anaerobic bacteria (*Pseudomonas denitrificans* grown under nitrate-reducing conditions). In contrast, *Pseudomonas aeruginosa* is able to convert dinitramide to nitrite, but only when NH_4^+ is present as a source of nitrogen. Dinitramide is biodegradable under anaerobic conditions when amended to a sulfate-reducing consortium taken from a lake sediment and sustained with lactate as the energy source.

6 Safe Handling of Ammonium Dinitramide

6.1 Disposal of Ammonium Dinitramide

During the first decade after ADN was discovered, chemists were mostly concerned about how to manufacture ADN in large quantities. Only after it became apparent that ADN might become a high-volume item did people start looking into the potential disposal problems when large quantities of ADN waste had accumulated in some locations. Propellant chemists had just witnessed the discovery of widespread pollution caused by perchlorates. ADN was intended as an environmentally friendly replacement for AP, and propellant chemists had to make sure that ADN would not cause the same type of environmental problems if it was spilled and found its way into the groundwater. For this reason, chemists started looking into safe disposal methods for ADN much earlier than their predecessors did for AP in the 1960s.

Demilitarization, neutralization, and disposal of energetic materials, including ADN and RDX, by hydrothermal hydrolysis methods in supercritical water has been studied extensively [475, 476]. This work was conducted with liquid water at autogenous pressures at temperatures over the range of 343–623 K (70–350 °C). The reactors included simple cuvettes placed in a thermostatted cell holder in either a UV spectrophotometer, sealed quartz bulbs, or stainless steel reactor bombs, and a spectrophotometric cell for work in the hydrothermal regime designed and built specially for this study. This has the advantage of water being a cheap reactant, with the ability to dilute the energetic materials to below the explosive threshold.

Various perchlorate cleanup methods are currently in use to remove perchlorate from surface waters, underground pollution plumes migrating in aquifers, and drinking water sources. One of these methods, bioremediation, has also been tested for disposal of dinitramide.

ADN can be destroyed through biodegradation by a mixture of denitrifying bacterial species. ADN was effectively mineralized in the anaerobic mixed culture, and the initial ADN concentration of 250 mg/L was reduced to non-detectable levels (>99% removal efficiency) by incubation under anaerobic conditions within 5 d [477]. Final products generated from anaerobic degradation of dinitramide by anaerobic metabolism were innocuous NH_4^+ , CH_4 , and CO_2 . The activity of denitrifiers was inhibited by high concentrations of ammonia generated through the degradation reactions of nitrite present as an additional contaminant.

Another method to destroy dinitramide and RDX is by reduction in alkaline solution (dispersion) at a pH of 12 with aluminum powder, accelerated by ultrasound sonication [114]. In the presence of 5 mg/mL aluminum powder and at a pH close to 12 (10 mM NaOH), 74% of the RDX and 86% of the ADN in near-saturated solutions decomposed within the first 20 min of sonication (20 kHz; 50 W). Sonication without Al powder and base caused minimal degradation of either RDX or ADN (~5–10%). Sonication at high pH in the presence of dispersed aluminosilicate, zeolite, alumina, or titanium dioxide also achieved only minimal degradation.

6.2 Environmental Fate of Ammonium Dinitramide

The environmental fate chemistry of ADN was investigated in detail to make sure that spilled ADN, a potential AP replacement, would not cause the same long-term problems as AP in the groundwater and aquifers [478]. The melting point of ADN is 365 K (92 °C), but it contrasts sharply with the melting point predicted with EPI Suite (518 K [245 °C]). However, empirical and modeled values for water solubility and vapor pressure agreed moderately well.

As part of such a study, the photolysis of ADN in natural waters was analyzed and modeled [267]. Photolytic rate constants for the photolysis of ADN were determined in order to better understand the fate of ADN in natural bodies of water. The validity of computer predictions was tested in field trials in Onondaga Lake, Syracuse, New York, USA. For summertime irradiation, half-life times of dinitramide anion ranged from ~6 min at the surface to ~15 years at a depth of 2 m.

ADN has a photolysis half-life on the order of minutes [479]. Based on a computer prediction, ADN is hydrolytically stable in water at all environmentally relevant pH levels from 2–10 at 25 °C, with an estimated half-life of about 370 years at pH 7. Bio-transformation of ADN in water and soil, under aerobic and anaerobic conditions, was not observed. Aqueous and solid ADN photolyzed in sunlight very rapidly, with half-lives of a few minutes in the summer and fall seasons, making photolysis the dominant loss mechanism for ADN in surface waters in all seasons. Quantum yields for ADN photolysis at 285–370 nm were 0.1 ± 0.02 for aqueous ADN solutions and 0.3–0.04 between 300 and 325 nm for solid ADN. Major decomposition products included nitrite and nitrate ions and N_2O , and their proportions were unaffected by oxygen, other cations present, or wavelength. Solid ADN gave NO, N_2O , N_2 , and nitrate ion. Co-metabolism with glucose did lead to rapid biodegradation of ADN over 65 h.

7 Safety Properties of Ammonium Dinitramide

Drop weight sensitivity, friction sensitivity, and electrostatic discharge (ESD) tests of four different types of ADN crystals were performed [30]. It was noted that powdered and prismatic crystalline ADN were less sensitive than a coagulated and a needle-type crystalline form. Drop weight test, friction test, DSC, bullet impact, ignition temperature by Wood's metal bath, and Koenen testing were reported in this paper [480]. The ADN used for this work was synthesized at the Swedish Defense Research Establishment (FOA) by a new method that is much less expensive than the conventional (SRI) method and is now in use by Bofors Explosives. The friction sensitivity of ADN is much lower than that of RDX. The impact sensitivity of ADN is of the same magnitude as that of RDX but varies a great deal with the shape of the particles; e.g., prilled ADN is nearly twice as insensitive as RDX. The reaction of ADN is also less violent. The ignition temperature was determined to be 160 °C (by Wood's metal bath). The ther-

mal stability, measured with microcalorimetry, showed that ADN is stable to at least 353 K (80 °C) and that impurities cause decreased thermal stability. The activation energy ($E = 158 \text{ kJ/mol}$) and frequency factor were determined from DSC data using the ASTM method E 698-79. It was also found that ADN in aqueous solution is sensitive to light.

To date, efforts to produce desensitized ADN and desensitized ADN propellants continue. In one such solicitation [481], the objective was to develop a process for desensitizing ADN or synthesis of an insensitive version of ADN containing comparable energy as prior art ADN. The objective would be to scale up the ADN desensitization process and produce material to conduct testing to demonstrate the desensitized nature of the newly developed ADN. One would then produce and test ADN-based formulations as AP replacements to show improved or at least comparable performance compared to currently fielded formulations. Such formulations could be used as propellants in base-bleed or rocket-assisted projectiles such as Excalibur 1b and XM1128, replacing AP-based base-bleed propellants with environmentally friendly ADN formulations.

Scaling up ADN production operations is not without hazards [482]. Three ADN synthetic methods were studied in order to estimate process safety for a planned increased production scale: from ammonia (method I), from urea (method II), or from potassium sulfamate (method III). The intermediates formed in these processes were identified, and their thermal stability was examined. DSC analysis showed that the intermediates in method II are unstable, readily decompose, and pose an explosion hazard. The intermediate in method III is more thermally stable and less hazardous than its counterparts in method II. The most suitable methods for large-scale processes are methods I and III. The preferred method for commercial large-scale ADN production, in terms of safety, would be method III.

7.1 Drop Weight Sensitivity of Ammonium Dinitramide

Although ADN has the advantage of lower friction sensitivity than RDX, ADN has the disadvantages of increased shock sensitivity and sensitivity to light and moisture. In the Bundesanstalt für Materialforschung und -prüfung (BAM) machine, the impact sensitivity of ADN was 50% point at 31 cm with a 2-kg weight, which was of the same magnitude as that of RDX but varied substantially with the shape of the particles. Prilled ADN was only half as sensitive as RDX and had a 50% point at 59 cm with a 2-kg weight [4].

The effect of hygroscopicity of ADN on its sensitivity was studied with samples conditioned at various controlled relative humidity levels ([123]; Table 24). For dry ADN, the investigators found that ADN is slightly more sensitive to impact and friction than RDX. ADN samples containing 0.5% H_2O were less sensitive than ADN containing only 0.02% H_2O . ADN containing only 0.3% hexamine as stabilizer was not much

different, but prilled ADN containing 2% hexamine was much more friction sensitive in the ABL friction test machine, close to the sensitivity of pentaerythritol tetranitrate (PETN).

Table 24: Drop weight, friction, and electrostatic discharge sensitivity of ADN.

Sample	Impact, 2.5 kg, 50% point, cm drop height	ABL friction, 50% point, lb _f	ESD sensitivity, 0.25 J
Neat ADN			
Dry (0.25% H ₂ O)	11–12	295–355	10/10 no fire
Not quite dry (0.5% H ₂ O)	11–12	295–355	10/10 no fire
Prilled ADN			
0.3% hexamine	11–12	295–355	10/10 no fire
2% hexamine	11	87	10/10 no fire

For comparison: HMX impact 20 cm, ABL friction 398 lbf

Data source: Chan et al. [123]

A high-speed photographic study was performed of the rapid deformation and possible initiation of ADN and GAP by drop-weight impact [483]. ADN was found to be more impact sensitive than AP, and it can be sensitized by both hard high-melting point grits (60-micron borosilicate or Pyrex glass shards) and brittle polymers, but high-density polyethylene powder would suppress deflagration.

Mixtures of ADN with CL-20 (30/70) have 10% more expansion energy than HMX but are very sensitive, comparable in sensitivity to lead azide [484].

ADN samples with a melting point of 363–365 K [90–92°C], decomposition point of 525 K [252°C], and density of 1.80 g/cm³ had an impact sensitivity H 50% of 24 cm with a 2-kg weight and a sample size of 30 mg [79].

The impact sensitivity of ADN was listed as 5 Nm (as synthesized) and 7.5 Nm (after emulsion crystallization) [105]. It is assumed that this is the 50% sensitivity point.

Both a Bureau of Explosives Impact Machine and a BAM Fallhammer apparatus were used in side-by-side tests to determine the sensitivity of ADN crystals, prills, and two propellants to drop-weight impact [165]. In the Bureau of Explosives impact test, about 10 mg of sample was subjected to an impact of a 3.6-kg mass dropped from a height of 102 mm. A positive reaction was recorded when the impact produced an audible report, visible flame, or smoke. Ten trials were performed on ten fresh samples while the drop height was held constant. The sample was considered as impact sensitive when positive events were observed in at least five out of ten trials. In the Bureau of Explosives Impact Machine, ADN crystals gave five positives out of ten, and ADN prills gave seven positives out of ten trials and thus is marginally sensitive. For the BAM Fallhammer Impact Test, about 40 mm³ of ADN was subjected to the impact of a mass (1 or 5 kg) dropped from a height of 15–50 cm. The limiting impact energy

for each sample was determined to be the lowest energy at which an explosion was obtained from at least one out of 6 six trials. An explosion was characterized by an audible report and/or a deformation of the impact assembly. Samples were considered impact sensitive if the limiting impact energy was equal to or less than 2 J. In the case of ADN in the BAM Fallhammer apparatus, the lowest energy at which a reaction was obtained was 4 J for both crystals and prills, and that is above (safer than) the 2-J limit. Some mixtures of ADN with solid fuels were much more impact sensitive than ADN by itself [485].

7.2 Friction Sensitivity of Ammonium Dinitramide

The friction sensitivity of ADN is much lower than that of RDX [4]. In the BAM friction sensitivity tester, the 50% point was above 35 kg_f (343 N). ADN samples with a melting point of 363–365 K (90–92 °C) and a density of 1.80 g/cm³ had a 14% friction sensitivity of 2.45 MPa (at 339 K [66 °C] with a 20-mg sample) [79]. Other sources report the friction sensitivity (point of beginning reaction) of ADN as 72 N [105]. For comparison, the impact sensitivity of the same sample of ADN was 5 Nm. The friction sensitivity of ADN was listed as >350 N [127]. A stabilized sample of ADN had a friction sensitivity of 54 N [110]. For comparison, the impact sensitivity of the same sample of ADN was 4 Nm. Additional friction sensitivity data are shown in Table 24.

7.3 Electrostatic Discharge Sensitivity of Ammonium Dinitramide

The ESD sensitivity of ADN is 0.45 J. The sensitivity to electrostatic discharge of ADN crystals, the prills, and two propellants was determined using an ESD apparatus manufactured by Franklin Applied Physics [165]. About 30 mm³ of sample was placed in a sample holder made from a nylon washer backed with a stainless steel disk. The sample holder was closed with a layer of adhesive tape. The limiting energy for ESD initiation was determined by subjecting fresh samples to sparks of varying energies. The test was also repeated with an open sample holder. Positive reaction was defined when the sample burned completely. Samples with limiting energies below 25 mJ were considered to be sensitive to ESD. All four ADN samples had limiting ignition energies greater than 156 mJ, and therefore they are not sensitive to ESD in either the closed or open sample holder. Additional ESD sensitivity data are given in Table 24.

7.4 Explosive Performance of Ammonium Dinitramide

7.4.1 Detonation Velocity of ADN

The detonation velocities of ADN were determined using cylinders of three different diameters of pressed ADN [484]. These were lightly confined in tubes of plexiglass and further enclosed in a larger-diameter tube of plexiglass. The cylinders of ADN were pressed axially to a density of 1.568 g/cm^3 , with a diameter of 25.1 mm and length 25 mm, and similarly to a density of 1.658 g/cm^3 for the larger cylinder with a diameter of 43.9 mm and a length of 40 mm. A 10-mm charge, similar in design to those described above, was also fired in an effort to determine the critical diameter, but no reaction at all could be measured. One can therefore assume that the critical diameter is $10 < d_{\text{crit.}} < 25.1\text{ mm}$. The detonation velocity in the 25-mm charge was $5.013 \pm 0.0407\text{ mm}/\mu\text{s}$, and the detonation velocity in the 43.9-mm charge was $5.260 \pm 0.0630\text{ mm}/\mu\text{s}$. Table 25 gives a comparison of the calculated and measured detonation properties of ADN.

Table 25: Detonation properties of ADN.

Density g/cm^3	Diameter mm	Detonation properties, measured		Chapman-Jouguet detonation properties, calculated	
		Velocity $\text{mm}/\mu\text{s}$	Pressure GPa	Velocity $\text{mm}/\mu\text{s}$	Pressure GPa
1.568	25	5.013 ± 0.0407	~ 16	6.950	16.45
1.658	43.9	5.260 ± 0.0630	18 ± 2	7.310	18.8

Data source: [484]

If you have some spare low-carat diamonds in your jewelry box and want to get rid of them really fast, try to mix them with ADN and measure the detonation velocity, as was done with ADN and nano-diamonds [486]. Detonation velocities of confined cylinders of melt-cast ADN/ZnO (99.5/0.5 by weight), ADN/nano-diamond/ZnO (92.4/

Table 26: Experimental and theoretical detonation characteristics of ADN.

		8074		23.72		[7]

7.2/0.4), ADN/AN/ZnO (95.5/4.0/0.5); and ADN/AN/ZnO/nano-diamond (88.0/4.5/0.5/7.0) ranged from 3.9 to 4.5 mm/ μ s in 1.3-cm diameter samples confined by steel and a 2.5-cm diameter ADN/AN/ZnO unconfined cylinder. Measured detonation velocities of ADN at different loading densities and charge diameters gave fairly good agreement with calculated values (Table 26).

7.4.2 Critical Density of ADN Detonations

Explosives can be classified into two types. For compounds of the first type, which includes high explosives (TNT, RDX, and others), the detonation velocity (D) increases linearly with an increase in density (ρ). Explosives of the second type are characterized by **non-monotonic** dependence $D(\rho)$. The detonation velocity for this type first increases with density and then passes through a maximum, and then detonation fails to propagate past a certain distance from the booster. These explosives of the second type are referred to as *non-ideal* explosives. The second type of explosives includes individual chemical compounds (AN, AP, **ADN**, nitroguanidine, HN) and many explosive compositions of the oxidant/fuel type. The reasons for such a behavior of $D(\rho)$ for individual explosives and explosive compositions are different [488]. An increase in density to 1.4–1.5 g/cm³ leads to the failure and termination of detonation propagation in ADN. This limit is diameter dependent.

7.4.3 Critical Diameter of ADN Detonations

The critical diameter of lightly confined ADN is $10 < d_{\text{crit.}} < 25.1$ mm [484].

7.4.4 ADN-Based Explosives

ADN is not a useful explosive by itself, but ADN is a very energetic oxidizer and can be combined with fuels or other explosives to form melt-castable explosives as potential replacements for TNT, tritonal, and amatol. The low melting point of ADN is usually a disadvantage for many of its applications as rocket propellant, but for melt-cast explosives, the low melting point makes it easier to safely process and pour the molten material.

One family of such melt-castable explosives is described in [489], where molten ADN forms the matrix in which other finely divided (but insoluble) explosives (RDX, HMX, CL-20) and metals (aluminum) can be suspended.

The shape of ADN for explosives is preferably prilled (spherical) particles. Although porosity of the prills may be undesirable for solid propellants, it may be acceptable for prills that are intended to be filled with organic oils and used as explosives [115]. See also [490]. Viton is a suitable binder for pressed ADN-based explosives [491, 492]; see Table 27.

Small-scale detonation velocity and plate-push tests were performed on ADN and aluminum (ADN/Al) pressed-powder composites [493]. The effects of varying the Al

Table 27: Explosive properties of ADN and pressable ADN/Al-based explosive compositions.

Composition	ρ , g/cm ³	D , km/s	$\rho/\rho_{\max}$, %
ADN	1.69	4.24	92.2
ADN	1.604	4.19	87.2
72/25 ADN/Al (3 μ m Al)	1.794	4.10	90.5
73/23/3 ADN/Al/Viton (50 μ m Al)	1.714	5.03	86.3
97/3 ADN/Viton	1.752	4.25	95.0
97/3 ADN/Viton	1.735	4.06	94.0

Data source: [491]

particle size in this mixture between 50 nm and 60 μ m revealed a large particle size dependency on the observed detonation velocities and the plate-push terminal velocities. The calculated detonation velocity for ADN was nearly twice the measured value. This discrepancy was explained on the basis that the major products of ADN decomposition are HNO₃ and NH₃ and that H₂O is only a minor constituent.

If AN in common emulsion explosives (which are typically sensitized by the addition of glass microballoons) is replaced with ADN, the brisance of the resulting explosive is increased by 60% [494]. That is comparable to or even higher than the explosive output of maximum-density trotyl.

Thermodynamic calculations of explosive performance of emulsion explosives containing energetic additives – propellants of various sorts and ADN – showed that the additives improved the properties of explosives: In the ideal-detonation approximation, AN-water-propellant-aluminum mixtures provided detonation velocities greater than 7000 m/s and detonation pressures of about 18 GPa [495]. ADN is more efficient: Replacement of AN in a model AN-water-saturated hydrocarbon-oleic acid mixture by ADN and replacement of glass microballoons by propellant enhanced the work function of industrial emulsion explosives by 60%.

The detonation velocity of melt-cast ADN was measured at charge diameters of 25–100 mm [193]. The detonation velocities were as follows: 25 mm, no detonation; 40 mm, 4.3 mm/ μ s; 60 mm, 5.4 mm/ μ s; 100 mm, 6.0 mm/ μ s. All data were taken at a density of 1.72 g/cm³. The 25-mm charge did not detonate, which indicates that the critical diameter for cast ADN is between 25 and 40 mm. The radius of the detonation curvature is dependent on the charge diameter and was 59, 76, and 137 mm, respectively. A cylinder test with a 51.95-mm inner diameter, 5-mm wall thickness and 300-mm length was also conducted. FOI Sweden has developed a method for melt-casting ADN that enables the melt casting of multi-kilogram charges at up to 99% of theoretical maximum density. After preliminary work with small charges, the casting process was scaled up to 6-kg charges. ADN proved to be relatively easy to cast when 1% of finely divided magnesium oxide (MgO) was added as nucleation kernels and stabilizer. It was found that melt casting in vacuum produced charges with lower densities. A number of basic parameters of importance to melt-casting

ADN were also determined: Shrinkage on solidification was 14%. A comparison with thermochemical equilibrium calculations (Cheetah 2.0) showed a large discrepancy between measured and predicted detonation velocity and Chapman-Jouguet (CJ) pressure, and the conclusion was that ADN is a strongly non-ideal explosive or even behaves as a non-CJ explosive. The detonation velocity in the cylinder test was low enough that CJ conditions at the front were probably never established.

ADN in mixture with aluminum powder makes a very powerful explosive [487]. The critical pressure of explosion initiation of ADN by itself is 0.80 ± 0.05 GPa for crystalline ADN and 1.12 ± 0.04 GPa for prilled ADN. The density at which a maximum detonation velocity was measured was between 1.4 and 1.6 g/cm³.

A melt-casting technique for ADN and ADN/aluminum was developed for cast explosive charges [139]. ADN proved relatively easy to cast when 1% of magnesium oxide was used as a stabilizer and crystallization kernels. Densities of ADN/MgO 99/1 were 92 to 97% of theoretical mean density, and those of ADN/Al/MgO 64/35/1 were between 95 and 99% of theoretical mean density. Sedimentation of Al in the melt was prevented and particle wetting was ensured by selecting a suitable particle size for Al. No gelling agents or surfactants were used to retard the settling of the Al particles. See also [496].

8 Applications of Ammonium Dinitramide

ADN is a useful oxidizer for solid propellants and monopropellants. Unconfirmed information indicated at one time that the Soviet Union may have fielded a weapon with an ADN-based solid propellant shortly after this oxidizer was discovered. No other fielded solid propellant application has become known in the interim. While HNF has insufficient thermal stability and a tendency to self-accelerating decomposition and therefore is less likely to ever find application in a solid propellant formulation, ADN can be qualified as medium-stable at lower temperatures, similar to nitrocellulose-based products. One must be aware that ADN also shows self-accelerated decomposition, but it can be stabilized. Some stabilizers are very effective. From the results presented, one can conclude that ADN has a chance to replace AP in propellants designed for selected applications [24]. A “universal” replacement application does not seem realistic at this time. Special measures such as coating of ADN particles may improve the situation, but the limited inservice temperature range will not be changed [497, 498].

ADN-based monopropellants can take credit for being the key ingredient in the first “green” less-toxic monopropellant to have flown in a satellite propulsion application (see *Encyclopedia of Monopropellants*, chapter “Ammonium Dinitramide-Based Monopropellants”).

9 Alkali Metal Dinitramide Salts

It is unlikely that alkali metal dinitramide salts will ever be used as rocket propellants. However, they are under consideration as replacements for KClO_4 (less corrosive exhaust products) and KNO_3 (more energetic) in pyrotechnic formulations such as igniters and charges for pyrovalves [499]. In the past, some alkali metal dinitramides have been used as intermediates in the preparation of ADN, but usually the preparations now go the opposite way because ADN is now the most readily available dinitramide salt (although it is rarely listed in chemical supply catalogs).

9.1 Production of Alkali Metal Dinitramide Salts

Alkali metal dinitramides can be prepared by at least three different methods [500]:

1. Reaction of metal hydroxides with β -substituted *N*-alkyl-*N,N*-dinitramines in ethanol:

where $\text{X} = -\text{CN}, -\text{CHO}, -\text{COR}, -\text{COOR}$, and $\text{M} = \text{K}, \text{Rb}, \text{Cs}$. This reaction works best for potassium, rubidium, and cesium dinitramide, which are poorly soluble in ethanol.

2. Cation exchange starting with potassium dinitramide obtained by the method above:

If the silver dinitramide is available, it can be reacted with any metal chloride or metal iodide to shift the equilibrium in the desired direction because the silver halogenide will precipitate.

3. Treatment of ADN with the metal hydroxide, allowing the liberated ammonia to escape:

Sodium, potassium, rubidium, and cesium dinitramide were synthesized in yields >70% by adding the corresponding alkali metal hydroxide starting from commercially available ADN, which was dissolved either in water or in methanol [501, 502]. First, a highly concentrated ADN solution (4.29 mol/L) was prepared. The synthesis of the salts was then done by adding the corresponding alkali metal hydroxide dissolved in

water or methanol to the ADN solution. The basic equation for the metathetical reaction is as follows:

where M = Na, K, Rb, Cs

The equilibrium can be shifted to the right by driving off the ammonia as a gas. Removal of water and liberated ammonia gas by freeze-drying gave the salts as white powders. Recrystallization gave the salts as crystalline plates (NaDN from nitromethane) or needles (KDN, RbDN, and CsDN from methanol). The lithium salt could not be recrystallized, and the freeze-dried material was used directly for analysis. The purification by recrystallization can be carried out from a highly concentrated water solution or in methanol as a solvent. Three of the alkali metal dinitramides (K, Rb, Cs) could be recrystallized from saturated water solutions. The yields of small (214 mmol) batches were 71–88%. The procedure of recrystallization out of a saturated water solution did not work for the very hygroscopic $\text{NaN}(\text{NO}_2)_2$ compound. It could be crystallized only by using the freeze-drying method described in the literature. The dinitramide salts were characterized by determining the melting point, by elemental analysis, by DSC, TGA (see more to follow), IR spectroscopy, and light microscopy investigations of the crystal shape. The recrystallized KDN consisted mainly of small cubes with a typical edge length of 0.2–0.3 mm. The results were in good agreement with the values mentioned in the literature. However, the DSC and TGA measurements showed some significant differences from previously published results. The X-ray structure analysis of $\text{RbN}(\text{NO}_2)_2$ showed an isomorphic structure in comparison to $\text{CsN}(\text{NO}_2)_2$.

In conventional metathetical reactions, product separation is based on solubility product differences (often using silver iodide as the insoluble product), and the resulting products are often impure and require purification by recrystallization. A new approach to product separation relies on the formation of an unstable, volatile by-product, such as ammonium methoxide $\text{NH}_4^+\text{CH}_3\text{O}^-$. This method provided very pure and anhydrous products in high yield and was demonstrated successfully for the syntheses of anhydrous cesium salts such as cesium perchlorate and cesium dinitramide [503].

Operating parameters in the synthesis of potassium dinitramide, an intermediate in the ADN synthesis, were optimized to reduce the costs of the ADN synthesis [504]. The optimal conditions for the synthesis of KDN, including nitrating agent:reagent molar ratio, nitration time, and temperature, were determined, and KDN was obtained in an approximate 48% yield.

9.2 Physical Properties of Alkali Metal Dinitramide Salts

Tables 28 and 29 present a summary of melting points of metal dinitramides and their CAS Registry Numbers.

Table 28: Melting points and CAS Registry Numbers of alkali metal dinitramide salts.

Cesium dinitramide has a melting point of 360 K (87°C) followed by the onset of exothermic decomposition at 448 K (175°C) (as observed by DSC). Its density is 3.05 g/cm³. The dinitramide ion in Cs N(NO₂)₂ is stable to base. Cesium dinitramide dissolved in water has a UV maximum at 284 nm with an absorption coefficient of $\epsilon(\text{H}_2\text{O}) = 4.24 \times 10^3 \text{ L mol}^{-1} \text{ cm}^{-1}$ [501].

The solubility of the alkali metal dinitramides in water decreases in the following order:

The densities of alkali metal dinitramides are summarized in Table 30.

9.2.1 Optical Properties of Alkali Metal Dinitramide Salts

The vibrational IR spectra and electronic spectra of KN(NO₂)₂ and other salts (Na, Li, NH₄, Fe, Ag, Mn, Mg, Rb, guanidinium [⁺C(NH₂)₃]) were first reported by Shlyapochnikov et al. [249] and later refined by the same author Shlyapochnikov et al. [211]. Dinitraminic acid salts of metal ions (with the exception of the mercury salt) have an ionic structure. Each possesses characteristic absorptions in the IR (1520–1540, 1430, 1180–1210, 1010–1035 cm⁻¹) and the UV ($\lambda_{\text{max}} = 223$ nm and 285 nm with a shoulder at 335 nm; $\epsilon = 5640$ L mol⁻¹). The IR and Raman spectra of solutions and melts of the salts indicate a C_{2v} symmetry. The complication of the spectra in the crystalline phase was explained by restructuring of the anion, which reduces its symmetry and makes the two nitro groups non-equivalent.

However, a KN(NO₂)₂ sample measured in the U.S. gave different results ([244]; Figure 73). The complication of the spectra in the crystalline phase has been explained by restructurization of the anion that reduces its symmetry and makes the nitro groups non-equivalent.

A comparison of the Christe et al. [244] results with those given previously by Shlyapochnikov for KN(NO₂)₂ shows significant discrepancies. Raman bands at 583 cm⁻¹ in the aqueous solution and at 640 and 204 cm⁻¹ in the solid state were not observed in the U.S. and most likely do not belong to the KDN sample. The previous polarization data given for the 1520 and 1436 cm⁻¹ bands are reversed: The 1520 cm⁻¹ band should be polarized, and the one at 1436 cm⁻¹ should be depolarized. Other Raman frequencies, relative intensities, and polarization ratios were also in poor agreement with the U.S. KDN data, while the agreement of the corresponding infrared data was somewhat better.

Figure 73: IR (top) and Raman (bottom) spectra of solid KDN. (Reprinted and modified from [244] with permission from © 1996 American Chemical Society.)

Some of the Shlyapochnikov assignments were later reexamined by Berger et al. [502]. According to Berger, the measured IR spectrum of $\text{KN}(\text{NO}_2)_2$ was comparable to the spectrum given by Shlyapochnikov et al. [210]. All described peaks were confirmed with a deviation of $\pm 5 \text{ cm}^{-1}$. The only deviation was a peak at 490 cm^{-1} , which was found by the Russian authors at a wavelength of 480 cm^{-1} . The IR spectrum of a Swiss $\text{KN}(\text{NO}_2)_2$ sample showed an additional small peak at a wave number of 1384 cm^{-1} . This could be the signal of the $-\text{O}-\text{H}$ vibration due to humidity. The IR spectrum of pure ADN did not show such a signal. A third type of IR spectrum of KDN is shown in Figure 74. The following assignments were made to the eight absorption bands seen in this spectrum (Table 31).

Similar salts are formed between methylnitroamine (methylnitramine) and alkali or alkaline earth metals. The IR and Raman frequencies of the K^+ , Rb^+ , Cs^+ , Me_4N^+ , Ca^{2+} , Ba^{2+} , and Mg^{2+} salts of MeNHNO_2 were not appreciably affected by the cation or by transition from the crystalline state to solution [507].

9.2.2 Thermodynamic Properties of Alkali Metal Dinitramide Salts

The enthalpies of formation and the enthalpies of solution in water of three alkali metal dinitramides are summarized in Table 32. Similar data are available for ammonium, guanidinium, and mono- and tri-aminoguanidinium dinitramides (See Table 40). Substitution of nitrate ion by dinitramide ion increases the enthalpy of formation of the alkali metal salts by approximately 230 kJ/mol (55 kcal/mol) (more positive, i.e., less-negative number). See also [508].

Table 32: Enthalpies of formation and enthalpies of solution of alkali metal dinitramides.

Compound	Enthalpy of formation		Enthalpy of solution	
	kJ/mol	kcal/mol	kJ/mol	kcal/mol
Sodium dinitramide	-230 ± 0.5	-54.94 ± 0.13	24.8 ± 0.04	5.93 ± 0.01
Potassium dinitramide	-264 ± 0.5	-63.14 ± 0.13	47.2 ± 0.08	11.28 ± 0.02
Cesium dinitramide	-274 ± 0.8	-65.38 ± 0.18	50.7 ± 0.08	12.12 ± 0.02

Data source: [195]

With the exception of the lithium salt, there are similarities in the structural parameters of the dinitramide ions. All have inequivalent N—N and N—O bond distances and nitro groups, which are twisted from the central NNN plane by varying amounts. Both the N—N distances and the NNN angles are intermediate between expected values for an sp^3 -hybridized or sp^2 -hybridized central nitrogen atom. It has been postulated that the twisting of the nitro groups is necessary to maximize the potential for conjugation with the lone pairs of the central nitrogen atom.

Diaquo-dinitramidato-lithium(I), $[\text{Li}(\text{N}_3\text{O}_4)(\text{H}_2\text{O})_2]$ and pyridinium dinitramide, $[\text{C}_5\text{H}_6\text{N}^+][\text{N}_3\text{O}_4^-]$, differ significantly in their cation-anion contacts [509]. The Li⁺ atom of the first is coordinated by two O atoms of the dinitramide anion in a chelate and by four additional water molecules, with the Li and central N atom of the anion on a twofold rotation axis. The pyridinium cation of the second exhibits a contact with the dinitramide anion via an intermolecular N—H $\cdots$ N hydrogen bridge. These

interactions are comparable to those found in anhydrous lithium dinitramide and ADN salts.

9.3 Chemical Properties of Alkali Metal Dinitramide Salts

9.3.1 Reactions of Alkali Metal Dinitramide Salts

The reactions of ADN with metals in solid propellants were discussed in Section 4.11.3.1. Additional applications of such mixtures with alkali metal dinitramides are in pyrotechnic igniters.

9.3.2 Thermal Stability of Alkali Metal Dinitramide Salts

The thermal behavior and hazards assessment of lithium, sodium, potassium, rubidium, and cesium dinitramide were studied using differential scanning calorimetry, thermal gravimetric analysis, differential thermal analysis, and hot-stage microscopy [501]. The metal dinitramides quantitatively decomposed to their respective metal nitrates, which were identified by mass spectrometry and X-ray diffraction [510]. The thermal stability study of the dinitramide salts of lithium, sodium, potassium, rubidium, and cesium revealed a complex set of DSC exothermic decays with the exception of the lithium salt, which showed two simple exothermic decomposition reactions [505]. The DSC trace of lithium dinitramide (LiDN) displayed two exotherms at 398 K (125 °C) (−298 J/g) and 455 K (182 °C) (−101 J/g). The melting endotherm occurred between the two exotherms at 430 K (157 °C) (+83 J/g) and corresponds to the melting of an initial decomposition product rather than LiDN itself. Sodium dinitramide (NaDN) gave a melting endotherm at 370 K (97 °C) (+54 J/g), followed by major and minor exotherms at 429 K (156 °C) (−946 J/g) and 483 K (210 °C) (−105 J/g) respectively. The potassium dinitramide (KDN) DSC trace displayed a large endotherm at 401 K (128 °C) (+96 J/g) corresponding to melting of KDN; however, it was preceded by a smaller exotherm (378 K [105 °C], −10.5 J/g) and endotherm (381 K [108 °C], +5.3 J/g). The observed endotherm at 381 K (108 °C) corresponds to the melting point of a KDN/KNO₃ eutectic. All five alkali metal dinitramide salts thermally decomposed to the equivalent nitrate salt as evidenced by DSC melting endotherms and TGA stoichiometric mass losses. Physical changes due to thermal heating were able to be followed by hot-stage microscopy. Thermal decay was usually accompanied by gas evolution.

All dinitramide salts, with the exception of LiDN, reacted violently under *temperature of ignition* test conditions (duplicate runs of 200-mg samples heated at 5 °C/min). Ignition occurred at 396–431 K (123–158 °C) for sodium, potassium, rubidium, and cesium dinitramide and was accompanied by an explosion or smoke. LiDN showed no ignition at temperatures up to 673 K (400 °C), but DSC for LiDN showed exothermic behavior at temperatures of 398 K (125 °C), yet no violent ignitions were observed under *temperature of ignition* test conditions.

DTA and X-ray photoelectric spectroscopy were used to investigate the thermal stability of KDN [511]. It was found that the decomposition product KNO_3 formed a eutectic system with KDN and decreased the liquefaction temperature of KDN. In continuation of this work, the thermal decomposition of KDN was investigated by DTA and FTIR [512]. The results showed that the decomposition of KDN in the solid state is different from that in the liquid state. The main condensed-phase product of the solid-state decomposition is KNO_3 . Some KNO_2 can also form. The melting point of the KNO_3 /KDN eutectic is about 382 K (109 °C).

The thermal stability of $\text{NaN}(\text{NO}_2)_2$, $\text{KN}(\text{NO}_2)_2$, $\text{RbN}(\text{NO}_2)_2$, and $\text{CsN}(\text{NO}_2)_2$ was measured by DSC and TGA [502]. The measured endothermicities of the dinitramide salts (melting of the dinitramide salts and the corresponding nitrates) were in good agreement with older literature data. However, some exothermicities showed significant differences compared with literature data. It was shown that the crystal modification influences the exothermic decomposition. Different crystallization and drying processes give crystals of varying stability. All dinitramide salts, with the exception of LiDN, reacted violently under temperature of ignition test conditions (duplicate runs of 200-mg samples heated at 5 °C/min). Ignition occurred at 396–431 K (123–158 °C) for sodium, potassium, rubidium, and cesium dinitramide and was accompanied by an explosion or smoke. LiDN showed no ignition at temperatures up to 673 K (400 °C).

The thermogram of $\text{KN}(\text{NO}_2)_2$ (Figure 75) showed a melting endotherm peaking at 398 K (125 °C), a decomposition exotherm peaking at 518 K (245 °C), and KNO_3 melting at 611 K (338 °C) [502]. According to the literature, KNO_3 has a melting temperature of 607 K (334 °C). Further investigations showed that the decomposition products of $\text{KN}(\text{NO}_2)_2$ are KNO_3 (90 mass-%) and KNO_2 (10 mass-%). A DSC thermogram of KDN at the heating rate of 10 K/min showed two endothermic peaks at 401 K (128 °C) and 611 K

Figure 75: DSC thermogram of KDN under argon. Heating rate 5 °C/min. (Republished and modified from [502], with permission of John Wiley & Sons Books; permission conveyed through Copyright Clearance Center Inc.)

(338 °C), the first one corresponding to melting of KDN (127 °C) and the second one to melting of KDN decomposition products, as well as a broad exotherm composed of two overlapping peaks, which were attributed to the decomposition of KDN.

ADN and KDN have similar structures, but KDN is more stable. After it was noted that the thermal stability of ADN is very sensitive to the presence of traces of moisture, it was suspected that a similar sensitivity might be found with KDN. Two types of KDN were synthesized and recrystallized in methanol with and without water and were tested for thermal stability [513]. A moist, not entirely dried sample melted at 404.0 K (130.9 °C). The thermal stability of both samples was evaluated by a pressurized DSC and TGA with heating rates of 10 to 30°/min. The PDSC pressure was either atmospheric pressure or elevated pressure at 3 or 6 MPa. In contrast to molten KDN, solid KDN decomposed rapidly. The absolutely dry KDN decomposed more rapidly than the partially moist KDN, an anomaly similar to what has been observed with ADN. For dried KDN, there was an exothermic peak at 364 K (91 °C) prior to the two endothermic peaks. At high pressures, the thermal decomposition of dry KDN was restrained. The exothermic peak at 364 K (91 °C) contracted gradually as the pressure was increased, and at 7 MPa it disappeared altogether. Pressure also had a distinct effect on the decomposition of liquid KDN. See also [514, 515] for information on the thermal stability of KDN and [516] for information on rubidium dinitramide. See also papers on the thermal decomposition of potassium dinitramide in the liquid state [517] or the solid state [518] or additional information by the same authors about other alkali metal dinitramides [519].

Unusual irregularities were observed for the decomposition of dinitramide metal salts in the solid phase: the solid-phase reaction was 10 to 10³ times faster than that in the melt, its rate had a sharp peak in the region of eutectics melting with the decomposition product (metal nitrates), and it was instantly inhibited by water vapor [506]. The addition of 10–15 mm Hg of water vapor at any stage of the dinitramide salt decomposition in vacuum immediately stopped the reaction. The injection of moist air acted in the same way. In the inhibited regime, the rate in the solid phase was lower than that in the liquid phase. No indications of such anomalous behavior were observed for the decomposition of guanidinium dinitramide. The formation of eutectics of dinitramide salts and the corresponding nitrates was studied using DSC. Rubidium, cesium, and guanidinium salts give these eutectics with melting points of 357.6 K (84.5 °C), 354.6 K (81.5 °C), and 401 K (128 °C), respectively. Li, Na, Rb, Cs, Ba, and guanidinium dinitramides were synthesized using literature methods [78, 520]. The products were twice recrystallized from ethanol or aqueous isopropanol and dried over P₂O₅ in a vacuum desiccator. These procedures rapidly decreased the water content to 0.2 to 0.4%, after which the drying process was sharply retarded. More drastic drying conditions (333–343 K [60–70 °C], vacuum) lowered the water content to 0.05% H₂O but were often accompanied by partial decomposition of the substance. Lithium and barium salts were synthesized only as low-melting crystal hydrates. They were dehydrated to 0.5% H₂O by drying over P₂O₅ at 253 K (–20 °C) in vacuum (0.01 mm Hg).

9.3.2.1 Radiolysis of Alkali Metal Dinitramide Salts

ADN-based propellants used for interplanetary missions may be exposed to cosmic radiation. No specific data exist for ADN, but KDN solutions 8.8×10^{-4} to 1.7 M, with a pH from 3.5 to 4.5, were used in dinitramide radiolysis experiments [521]. The solutions were prepared using bidistilled, deaerated water; were saturated with argon; and were irradiated in sealed glass tubes 1 cm in diameter. The samples were irradiated with ^{60}Co γ rays and with 4.8-MeV electrons from an accelerator. The absorbed dose rate was determined with a ferrous sulfate dosimeter. The concentration of surviving dinitramide anions was determined spectrophotometrically from the absorption at 285 nm. The formation of produced nitrite ions was monitored colorimetrically by the Griess diazo dye method. In the presence of added ethanol or *tert*-butyl alcohol, the decomposition rate increased remarkably, whereas the saturation with N_2O gas stabilized the anion. In diluted aqueous solutions, water radiolysis products reduced the dinitramide anion to nitrite ions, with the radiation chemical yield depending on the absorbed dose rate. In concentrated KDN solutions, the radiation chemical yield of nitrite ions was considerably higher, which was explained by a mechanism of direct action of irradiation on the dinitramide anion.

9.3.3 Strand Burning Rates of Alkali Metal Dinitramide Salts

Since KDN does not include any combustible species such as NH_4 , one can study the decomposition of the $-\text{N}(\text{NO}_2)$ anion by itself. If a binder is used, one would expect that most active radicals will react with an external fuel, resulting in an increase in the temperature of the rate-controlling zone. Two reaction pathways were proposed for KDN decomposition: a solid-state decomposition with formation of KNO_3 and N_2O and a liquid-phase decomposition with formation of $\text{KNO}_3/\text{KNO}_2$ and $\text{N}_2\text{O}/\text{NO}$:

However, data of both DSC and TGA suggest that the decomposition of KDN can not be satisfactorily described by this equation alone. An approximate overall equation for the decomposition of KDN would be

Burning rates of KDN and its mixtures with a nitrate ester binder were measured in a window constant-pressure bomb of 1.5-L volume in the 0.1–15 MPa pressure interval [522]. Samples to test were prepared by pressing fine particles of KDN into transparent acrylic tubes of 4-mm internal diameter. KDN by itself in the form of pressed cylinders with an average density of 2.1 g/cm^3 (i.e., 95% of crystal density 2.209 g/cm^3) confined into acrylic tubes 4 mm in diameter started burning at a pressure of 0.2 MPa with a burning rate of 5 mm/s. The log burn rate versus log pressure diagram of KDN showed a kink (break point, a sudden change of slope) at 5 MPa and 8 mm/s. The adi-

abatic combustion temperature of KDN is low: 1410 K at 10 MPa. KDN burned without a luminous flame, leaving a white residue in the form of small solidified drops.

9.3.4 Safety Properties of Alkali Metal Dinitramide Salts

A hazard assessment of Li, Na, K, Rb, and Cs dinitramides showed that the metal dinitramides were insensitive to impact and friction and moderately insensitive to electric discharge, but they were relatively unstable when heated under vacuum stability testing conditions [501]. The drop weight sensitivity of both KDN and CsDN was above 20 J, the friction sensitivity was above 360 N, and the ESD sensitivity was above 5.6 mJ [499].

The metal dinitramide salts showed varied responses to electrostatic discharge. LiDN proved to be the most sensitive, with initiation occurring above the 0.045 J level. CsDN displayed intermediate sensitivity, while NaDN, KDN, and RbDN could not be initiated at a 4.5-J discharge. Table 34 gives a summary of the safety properties of alkali metal dinitramides.

Table 34: Safety properties of alkali metal dinitramides and ADN.

	Density	Gas evolved	BAM friction	Electro-static discharge	Temperature of ignition		Vacuum stability (80 °C/40 h)
	g/cm ³	mL	N	J	K	°C	mL/5g
LiN(NO ₂) ₂	2.15–2.19	140 (1.6)	>360	0.045	>673	>400	Excess gas
NaN(NO ₂) ₂	2.09	>145	>360	4.5	396	123	Excess gas

CsN(NO ₂) ₂	3.07	>145	>360	0.45	428	155	25.5
For comparison: NH ₄ N(NO ₂) ₂	1.81	30 (2.3)	360	0.45	415	142	0.73

Data source: [501]

9.3.5 Applications of Alkali Metal Dinitramide Salts

The primary application for alkali metal dinitramides, in particular KDN, would be in pyrotechnic formulations as a replacement for KClO₄ or KNO₃. NaDN would not be suitable for any such application because it is very hygroscopic. The need to replace KClO₄ or KNO₃ in pyrotechnic formulations is not as urgent or driven by environmental concerns as the reasoning for replacement of AP by ADN because the quantities of pyrotechnic igniters involved are so much smaller than the amount of perchlorates used in launch vehicle boosters and military intercontinental ballistic missiles.

KDN was used as an oxidizer for pyrotechnic compositions containing boron or magnesium [523] and for boron-based flare compositions [524].

The thermal stability and safety properties of mixtures of KDN with Ti metal were examined as another example for pyrotechnic applications of KDN [499]. Researchers conducted a systematic investigation of the pyrotechnic redox systems KDN/titanium and cesium dinitramide/titanium for a wide range of O/F ratios. The heats of reaction as well as the burning rates of KDN/titanium are higher than those of cesium dinitramide/titanium. Both systems have a moderate sensitivity to friction and electrostatic discharges. However, both mixtures suffer from a very high sensitivity to impact. These sensitivities are in the same range as pure HMX or PETN. KDN can be used as the oxidizer in red flare compositions that would not leave perchlorate residues [525].

Another potential application of KDN would be as a stabilizer for AN [72]. While KNO_3 has been used for decades as a stabilizer for AN in solid propellant and gas generant formulations, the disadvantage of KNO_3 is that it reduces the performance of AN as a rocket propellant. KDN, however, more than compensates for the performance loss due to the introduction of the potassium [513, 526].

With the addition of only 5% KDN, AN can be phase-stabilized, and an increase in the percentage addition of KDN in AN crystals will boost the energy capacity of AN [58, 527, 528]. The phase transition of AN at 330.79 K (57.64 °C) was completely removed in the presence of 3% of KDN. For AN/KDN propellant systems, a maximum of 30% KDN can be added to AN. The reason lies in the decomposition mechanism of KDN.

10 Dinitramide Salts of Other Metals

Dinitramide salts of other metals have been prepared and characterized, but they are of no interest as rocket propellants and have only limited potential as ingredients in pyrotechnic formulations. Transition metal dinitramides may be useful as burning-rate catalysts in ADN-based solid propellants. They would be added only in small percentages.

Salts described in the literature include $\text{AgN}(\text{NO}_2)_2$, $[\text{Ag}(\text{CH}_3\text{CN})][\text{N}(\text{NO}_2)_2]$, $[\text{Ag}(\text{py})_2][\text{N}(\text{NO}_2)_2]$, $[\text{Cu}(\text{NH}_3)_4][\text{N}(\text{NO}_2)_2]$, and $[\text{Pd}(\text{NH}_3)_4][\text{N}(\text{NO}_2)_2]_2$ [529]. Silver dinitramide is useful in the synthesis of other dinitramide salts when the other cation is introduced as the chloride or bromide. When crystallizing from acetonitrile or dioxane solution, it will retain part of the solvent as a solvate.

Electronic and vibrational spectra of mercury(II) dinitramide $\text{Hg}(\text{N}_3\text{O}_4)_2$ show that in the crystalline state and in solutions in non-polar solvents, it is a covalent compound, the mercury atom being bound to the oxygen atoms [530]. In polar solvents, it dissociates to give mercury(II) cation and dinitramide anion N_3O_4^- . This salt can be used as a reagent for mercuration, an addition reaction where mercury is added to the double carbon-carbon bonds, for alkylation, and for complexation in organic chemistry [531].

The crystal structures of the hexaaquomagnesium, hexaaquomanganese, and hexaaquozinc dihydrate salts of dinitramide have been determined [532]. The properties are listed in Table 35.

Table 35: Crystal structures of magnesium, manganese, and zinc dinitramides.

Compound	Space group	<i>a</i> , Å	<i>b</i> , Å	<i>c</i> , Å	β , °
Hexaaquomagnesium dinitramide	$P2_1/m$	9.589(2)	7.420(1)	11.116(2)	108.25(3)
Hexaaquomanganese(II) dinitramide	$P2_1/m$	9.623(4)	7.477(2)	11.274(3)	108.38(3)
Hexaaquozinc dinitramide dihydrate	$P2_1/m$	9.513(1)	7.4270(8)	11.164(1)	108.806(6)

Data source: [532]

The three structures are isostructural, consisting of hexaaquo cations, dinitramide anions, and water molecules interlinked by extensive 3D hydrogen-bonding interactions. All oxygen atoms as well as the central nitrogen atom of the dinitramide anion are involved in acceptor hydrogen bonds with neighboring water protons.

Attempts to obtain the dinitramide salts of Cu(I), Al(III), Cr(III), or Fe(III) have failed. The melting points of other metal dinitramides are summarized in Table 36.

Table 36: Melting points of metal dinitramides.

The thermal decomposition of silver dinitramide, $\text{AgN}(\text{NO}_2)_2$, was investigated using DSC, TGA, FT-IR, Raman spectra, and XRD [533]. The results showed that the degradation process of $\text{AgN}(\text{NO}_2)_2$ could be divided into two stages. The first stage, with a mass loss of 21.9%, took place in the 408–483 K range, during which N_2O was released and the intermediate product of thermal decomposition was AgNO_3 . The second stage, with a mass loss of 28.2%, occurred at 483–800 K, with evolution of NO_2 and O_2 and Ag metal as the final product of thermal decomposition.

11 Dinitramide Salts of Nitrogen-Containing Bases

The dinitramide salts of organic nitrogen-rich bases are particularly useful as rocket propellants and gas generants. The alkylammonium dinitramides were studied as additives to change the crystal habits of ADN and allow the production of more compact crystals with lower length/diameter ratios that would pack better in a solid propellant (Section 2.5.2). These salts are discussed under their parent base along with the nitrates and perchlorates, most of them in *Encyclopedia of Liquid Fuels*, chapter “Aliphatic Amines.” In this chapter we only provide a comparison of physical properties of the dinitramide salts of a wide range of nitrogen-containing bases, mostly alkyl amines and heterocyclic amines. Following the summary overview, a few selected amine dinitramide salts are discussed in detail. There is some duplication between the following section and *Encyclopedia of Liquid Fuels*, where the amines that form the cation are discussed in detail, along with their salts.

Hydrazinium(1+) dinitramide, $[\text{N}_2\text{H}_5][\text{N}(\text{NO}_2)_2]$, $\text{N}_5\text{H}_5\text{O}_4$, HDN, CAS RN [165603-97-4], is discussed in *Encyclopedia of Oxidizers*, chapter “Hydrazinium Salts.”

Hydroxylammonium dinitramide is described in *Encyclopedia of Oxidizers*, chapter “Hydroxylammonium Salts.”

11.1 Melting Points of Dinitramide Salts of Nitrogen-Containing Bases

Table 37 is a summary of the melting points of the dinitramide salts of organic bases. There is a similar table with enthalpies of formation of these compounds in Section 11.3.2.

The simplest method for preparation of alkylammonium dinitramides is the neutralization of the amine with dinitraminic acid in solution. This is used for the weak amines with basicity constants less basic than ammonia. Stronger base amines can be reacted with ADN, and the liberated ammonia is driven off. These two methods were used for preparation of the salts listed in Table 38 [537].

Table 37: Melting points of dinitramide salts of organic bases.

11.2 Thermal Stability of Dinitramide Salts of Nitrogen-Containing Bases

Thermograms of two of the dinitramide salts from organic bases are shown in Figures 76 and 77. The thermal stability of the guanidinium dinitramide is remarkable, but the cause of the first endotherm at 380.2 K (107.1°C) prior to melting has not been explained (an impurity or a phase transition?). See also [538, 539].

Figure 76: DSC and TGA thermogram of guanidinium dinitramide. (Reproduced and modified from [537].)

Unlike alkali metal dinitramide salts, the guanidinium salt does not exhibit abnormal solid-phase decomposition rates. The rates in vacuum and in air are equal, and no increase in the rate is observed at the point of the eutectic melting with guanidinium nitrate, which is 401 K (128 °C). The rate in the solid state is 400 times slower than in the liquid phase.

The thermal stability of ADN/GUDN mixtures was discussed in Section 4.10. GUDN has excellent thermal stability and is not hygroscopic. The thermal decomposition of GUDN has been studied by non-isothermal TGA and TGA combined with mass spectrometry (TGA-MS) [540]. Additional information on GUDN will be provided in *Encyclopedia of Liquid Fuels*, chapter “Amides and Imides.”

Figure 77: DSC and TGA thermogram of ethylenediammonium bis-dinitramide. (Reproduced and modified from [537].)

Guanidinium dinitramide, GuDN, $[\text{NH}_2\text{C}(\text{NH}_2)\text{NH}_2][\text{N}(\text{NO}_2)_2]$, can be synthesized from guanidinium carbonate and ADN. Two different crystalline forms (α -type and β -type) were obtained depending on the applied solvents and synthesis conditions [541]. Water might become trapped in a crystal lattice between the inner molecules during crystallization. Despite having the same chemical composition, Raman-IR and TGA-DSC revealed different physical characteristics of the two modifications. Peaks of Raman shift near 1000 cm^{-1} implied different chemical structures. Thermal analysis revealed an exothermic temperature of 428.8 K (155.7°C) for α -type but one of 464.7 K (191.6°C) for β -type. The caloric value of the exotherm of α -type was 536.4 J/g and that of the β -type was 1310 J/g . While the synthesized GDN of α -type showed a steep exothermic decomposition, the β -type decomposed slowly after melting through an endothermic process. This implied that despite the same molecular formula, some different molecular-structure thermal properties were formed depending on synthesis conditions.

11.3 Thermodynamic Properties of Dinitramide Salts of Nitrogen-Containing Bases

11.3.1 Heat of Solution of Dinitramide Salts of Nitrogen-Containing Bases

The heats of solution of dinitramide salts of nitrogen-containing organic and inorganic bases in water at infinite dilution were measured in comparison to the corresponding nitrate salts. The results are summarized in Table 39. Some of these salts are useful intermediates in the production of ADN, or they can be used as propellant ingredients in their own right.

Table 39: Enthalpies of solution of amine salts of dinitramidic acid and nitric acid.

11.3.2 Enthalpy of Formation of Dinitramide Salts of Nitrogen-Containing Bases

A summary of the enthalpies of formation of dinitramides of nitrogen-containing bases in comparison to a few alkali metal dinitramides is given in Table 40. These enthalpies of formation were derived from calorimeter measurements in a combustion bomb and from measurements of the heats of solution in water. In addition, the enthalpies of formation of individual ions dissolved in water in infinite dilution were calculated from heat-of-solution measurements and tabulated for comparison.

For the same cation, the difference in the enthalpy of formation of the dinitramide salt and the nitrate salts is typically of the order of 230 kJ/mol (55 kcal/mol).

Table 40: Recommended values of the enthalpies of formation (ΔH°_f) of cations and amine salts of dinitramidic acid and nitric acid.

11.4 Other Properties of Dinitramide Salts of Nitrogen-Containing Bases

A series of long-chain alkyl diamines, amino acids, and aromatic diamines was tested as additives to modify the crystallization habits of ADN [97]. The strategy was unsuccessful, but in the process butanediammonium bis(dinitramide) (BDDN) was isolated and characterized. BDDN has a similar space group to ADN, and its habit is sensitive to growth conditions, crystallizing in short prisms and two types of blades. For these reasons, the growth behavior and surface and packing structure of BDDN was analyzed in the hope that these might give some clues to ADN habit modification.

A large number of dinitramide salts of organic amines were synthesized and their physical properties measured [520]. This included properties of dinitramide salts with ammonia, hydrazine, hydroxylamine, and formamidine and their alkylated and aminated derivatives. In addition, strand burning rates were measured [449]. Table 41 gives a summary of melting points, ignition temperatures, pressed densities, and calculated enthalpies of formation of a group of dinitramide salts of organic amines. The Roman numeral in the “preparation method” column designates salts that were prepared from ADN and the free amine by elimination of ammonia (**I**), boiling of carbonates of the amine with ADN in alcoholic solution (**II**), or precipitation of barium sulfate from solutions of amine sulfates and barium dinitramide (**III**). The burning rates of strands pressed into tubes 4–7 mm in diameter and burned at 150–200 MPa were measured as a function of pressure, and the pressure coefficients were derived from logarithmic graphs. The substitution of an organic amine for ammonium in the dinitramide salt will result in different flame temperature, temperature at the surface, and reactivity of the fuel. The surface temperature can be assumed by analogy with other salts to be determined by the salt dissociation reaction, and thus it will depend on the amine basicity. It was attempted to obtain a correlation between the basicity constant of the amine and the burning rate of its dinitramide salt, but not all data fit into the same scheme. Looking at the burning rate data, the salts could be divided into three main groups according to their burning characteristics:

- (1) dinitramide salts like ADN, the burning rate-pressure dependence of which includes a region of combustion instability;
- (2) salts that show a transition region characterized by a reduced pressure exponent on the $r_b = f(p)$ curve in the medium pressure range; this group includes dinitramide salts of amines of both high and low basicity;
- (3) salts that demonstrate stable combustion, showing invariant pressure exponent throughout the entire pressure range; these include salts of amines of low basicity, e.g., 5-aminotetrazole or *m*-nitroaniline.

The heat of formation measured for guanidinium dinitramide at Los Alamos National Laboratory (LANL) is -40.7 ± 1.5 kcal/mol. Thus, the guanidinium derivative has a fairly high heat of formation as compared to the perchlorate (-74.1 kcal/mol) or nitrate salts (-93 kcal/mol) of guanidine. The DSC of guanidinium dinitramide shows

Table 41: Summary of physical properties of dinitramide salts of organic amines.

Compound	Preparation method	Density of pressed strand g/cm ³	Melting point °C	Ignition point °C	Enthalpy of formation		References
					kJ/mol	kcal/mol	
Aminoguanidine dinitramide	II	1.63	87–88	205	–48	–11.5	[520]

Butane diammonium dinitramide	I	1.548	67–73				[97]
Urotropinium dinitramide			121–124				[529]

what appears to be a phase change at around 373 K (100 °C), with the melting point onset near 413 K (140 °C). This melting point is surprisingly high for a dinitramide salt and is only matched or exceeded in the cubane amine derivatives.

11.5 Individual Dinitramide Salts of Nitrogen-Containing Bases

There is a large group of energetic material salts synthesized by combining an energetic amine (e.g., the amine of a strained-ring caged or heterocyclic compound) cation with an energetic anion such as dinitramide. Several examples are shown in the following paragraphs, including cubane-1,4-diammonium dinitramide and cubane-1,2,4,7-tetraammonium dinitramide [164, 534].

11.5.1 Dinitramide Salts of C₁ Nitrogen-Containing Bases

In the preparation of ADN, instead of trying to isolate the product as the very soluble ADN, it is easier to isolate the dinitramide salt in the form of the poorly soluble guanidinium dinitramide, which precipitates, filtered, washed, and dried; and can later be converted to ADN [41]. Guanidinium dinitramide is described in detail in *Encyclopedia of Liquid Fuels*, chapter “Amides and Imides.”

11.5.2 Dinitramide Salts of C₂ Through C₃ Nitrogen-Containing Bases

Ethylenediamine (1,2-diaminoethane) forms a diprotonated salt, ethylenediammonium(2+) bisdinitramide, C₂H₁₀N₈O₈, with dinitramidic acid, which is of interest as an energetic additive to propellants and gas generants [536]. The salt crystallizes in the triclinic space group *P*1 with cell dimensions $a = 5.614(1)$, $b = 6.867(2)$, $c = 7.371(2)$ Å, $\alpha = 68.89(2)$, $\beta = 89.00(2)$, $\gamma = 78.90(2)^\circ$, $Z = 1$, and $\rho_c = 1.753$ g/cm³. Atomic coordinates, bond lengths, and angles and equivalent isotropic displacement parameters for the salt were calculated and tabulated. These cations provide a constrained local environment for the dinitramide anions because of extensive hydrogen bonding.

Ethylenediamine as a ligand in transition metal complexes forms complex dinitramide salts [542]. Complexes of nickel(II), cobalt(III), copper(II), zinc(II), and cadmium(II) with ethylenediamine containing the dinitramide anion were synthesized and characterized by NMR, ESP, and DTA.

11.5.2.1 N-Guanyllurea Dinitramide

N-guanyllurea dinitramide, also known as GUDN, [H₂NC(=N⁺H₂)NHCONH₂][−] [N[−](NO₂)₂], C₂H₇N₇O₅, FOX-12, CAS RN [217464-38-5], an energetic material developed in Sweden by FOI, has low sensitivity and good potential for use as a propellant ingredient, gas generant, or insensitive explosive. It is already being used in gas generators for automotive airbags, which was the first full-scale application of any

dinitramide outside of Russia. Properties of *N*-guanylurea dinitramide are described in more detail in *Encyclopedia of Liquid Fuels*, chapter “Amides and Imides,” under the cation of this compound, rather than here under the anion of this compound. (We are used to naming salts with the cation first, so that is where these salts are listed.) *N*-guanylurea dinitramide is underoxidized with an oxygen balance of -19.1% , so it should not be discussed here under solid propellant oxidizers.

11.5.3 Other Dinitramide Salts of Organic Bases

11.5.3.1 Biguanidinium Dinitramides

Three different biguanidinium salts of dinitramidic acid were prepared and structurally characterized based on X-ray diffraction data [543]. Details about these salts are presented in *Encyclopedia of Liquid Fuels*, chapter “Amides and Imides.” See also [544].

11.5.3.2 3,3-Dinitroazetidine Dinitramide

3,3-dinitroazetidine is an explosive in its own right. Its explosive power and oxygen balance can be improved by forming the dinitramide salt of the amine, called dinitroazetidinium dinitramide [535].

11.5.3.3 Dinitramide Salts of 3,4,5-Triamino-1,2,4-triazole

The dinitramide salts of 3,4,5-triamino-1,2,4-triazole and similar heterocyclic amines are of interest as ionic liquids since they melt below 373 K and can be used as monopropellants. The thermal decomposition of 3,4,5-triamino-1,2,4-triazole dinitramide was measured using a microcalorimeter at four different temperatures under atmospheric pressure [545]. The apparent activation energy and pre-exponential factor of the exothermic decomposition reaction are 165.57 kJ/mol and $10^{18.04} \text{ s}^{-1}$, respectively. The critical temperature of thermal explosion is 432 K. The entropy of activation (ΔS), enthalpy of activation (ΔH), and free energy of activation (ΔG) are $97.19 \text{ J mol}^{-1} \text{ K}^{-1}$, $161.90 \text{ kJ mol}^{-1}$, and $118.98 \text{ kJ mol}^{-1}$, respectively. The self-accelerating decomposition temperature (T_{SADT}) is 422 K. The specific heat capacity as a function of temperature of 3,4,5-triamino-1,2,4-triazole dinitramide was determined by a micro-DSC method and a theoretical calculation method:

$$C_p = 0.252 + 3.131 \times 10^{-3} T \quad (\text{for the range } 283.1 \text{ K} < T < 353.2 \text{ K})$$

where C_p is the heat capacity in $\text{J g}^{-1} \text{ K}^{-1}$ and T is the temperature in kelvin. The molar heat capacity of 3,4,5-triamino-1,2,4-triazole dinitramide is $264.52 \text{ J mol}^{-1} \text{ K}^{-1}$ at 298 K. See also [546].

11.5.3.4 Dinitramide Salts of Higher ($C_{n>3}$) Nitrogen-Containing Bases

Hexamethylene tetramine (“hexamine,” urotropine) forms monoprotonated salt crystals with different structures with dinitraminic acid, depending on the solvent

from which they are crystallized [536]. Recrystallizing the dinitramide salt of hexamine from polar organic solvents led to the triclinic polymorph, while recrystallizing it from water gave the monoclinic polymorph. The unit cell dimensions of the triclinic space group $P1$ polymorph are $a = 6.391(2)$, $b = 7.5826(9)$, $c = 10.828(1)$ Å, $\alpha = 77.58(1)$, $\beta = 88.18(2)$, $\gamma = 87.54(2)^\circ$, $Z = 2$, and $\rho_c = 1.604$ g/cm³, while the other polymorph crystallizes in the monoclinic space group $P2_1/c$ with cell dimensions $a = 6.4893(3)$, $b = 14.5149(8)$, $c = 10.6557(4)$ Å, $\beta = 94.300(4)^\circ$, $Z = 4$, and $\rho_c = 1.641$ g/cm³. Atomic coordinates, bond lengths, and angles and equivalent isotropic displacement parameters for the salts were calculated and tabulated. These cations provide a constrained local environment for the dinitramide anions because of extensive hydrogen bonding. The amount by which the nitro group has rotated out of the N2–N1–N3 plane varies substantially between these salts and ethylenediammonium(2+) bisdinitramide, which was analyzed for comparison.

Other isocyclic organic amine salts include cubane-1,4-diammonium dinitramide and cubane-1,2,4,7-tetraammonium dinitramide [164, 534].

A series of new energetic salts based on the polyamino-1-guanyl-triazole cation with three to five amino groups and the dinitramide anion were synthesized and characterized [547]. These new nitrogen-rich salts tend to have extensive hydrogen bonding, and they have high densities and good thermal stabilities. The impact of multiple amino groups in the cation of the dinitramide salts was then systematically investigated. Their properties were modified by varying the guanyl substituents and/or the amino substituents on the triazole ring. On the basis of theoretical calculations, 3,5-diamino-1-guanyl-1,2,4-triazole dinitramide has higher detonation pressure and velocity values than the dinitramide energetic materials such as ADN and *N*-GUDN (FOX-12). The structures of other salts (3-amino-1-guanyl-1,2,4-triazole dinitramide, 3,5-diamino-1-guanyl-1,2,4-triazole dinitramide, 5-amino-*N*-amidino-1-guanyl-1,2,4-triazole dinitramide, and 3,5-diamino-*N*-amidino-1-guanyl-1,2,4-triazole dinitramide) were investigated using single-crystal XRD analysis.

The dinitramide and the nitrate salts of the 2,4,6-triamino-1,3,5-triazinium(1+) (“melaminium”) cation were prepared, and the crystal structures were identified based on X-ray single-crystal diffraction data [548]. 2,4,6-triamino-1,3,5-triazinium (melaminium) dinitramide crystallizes in triclinic crystals, space group $P\bar{1}$, $a = 6.6861(11)$, $b = 6.9638(16)$, $c = 10.447(2)$ Å, $\alpha = 99.07(3)$, $\beta = 98.30(3)$, $\gamma = 108.50(3)^\circ$, $V = 445.6(2)$ Å³, and $Z = 2$. For comparison, melaminium nitrate crystallizes in monoclinic crystals, space group $P2_1/c$, $a = 3.5789(7)$, $b = 20.466(4)$, $c = 10.060(2)$ Å, $\beta = 94.01(2)^\circ$, $V = 735.0(3)$ Å³, and $Z = 4$. The crystal structures of both salts showed distinct monoprotonated melaminium cations and dinitramide or nitrate anions, respectively. Efficient packing in the solid state and decent thermal stability are achieved by extensive hydrogen bonding between two-dimensional zigzag ribbons of the melaminium cations and the respective anions. This results in high densities of the solid-state structures of 1.74 and 1.71 g/cm³, respectively.

3-Amino-1,2,4-triazolium dinitramide was synthesized through the combination of 3-amino-1,2,4-triazole cation and oxygen-rich dinitramide anion, and its structure was confirmed using single-crystal XRD, elemental analysis, FTIR, UV-Vis spectrometry, and NMR [549]. The thermal stability was studied using DSC, TGA, and TGA tandem IR. Results indicated that this salt was thermally stable up to 439 K. The activation energy of the decomposition reaction was $E_a = 281.9 \text{ kJ/mol}$.

A polymeric polyethylene with intermittent amino groups is a polymeric base that can form dinitramide salts that can be used as solid propellants [550].

11.6 Other Inorganic Nitramine Compounds

While dinitramine and its salts are already quite powerful oxidizers, one is left to wonder whether the oxidizing power of nitramine could possibly be increased by replacing one of the hydrogens on the amino group with fluorine. The fluoronitramide anion, $\text{O}_2\text{N}-\text{N}^-\text{F}$, in the form of its potassium, tetraisopropyl-*p*-phenylenediguanidinium, and tetraphenylphosphonium salts, has been synthesized [551]. The tetraphenylphosphonium fluoronitramide was characterized in detail as it was by far the most stable. The free acid $\text{HFN}-\text{NO}_2$ was found to be unstable, as was the ammonium salt of fluoronitramide. The fluorine atom was shown to be easily replaced by nucleophiles. In contrast to dinitramide, which at room temperature is unreactive toward aqueous alkali, fluoronitramide reacts instantly with aqueous hydroxide.

Another potential high-energy oxidizer is ammonium di (nitramido) amine (ADNA)

Di(nitramido)amine is a hypothetical compound, but this has not prevented imaginative chemists from including it in an environmental-fate evaluation of high-energy oxidizers [478, 552]. The predicted density is $\rho = 1.76 \text{ g/mL}$, and the predicted enthalpy of formation is $\Delta H_f = +180 \text{ kJ/mol}$ (+43 kcal/mol). The results suggest that ADNA is hydrophilic and highly water soluble (115600 mg/L) and not likely to bioaccumulate.

Another unusual nitrogen–oxygen compound and potential rocket propellant is dinitrosohydrazine, which so far is known only in the form of its salts. Dinitrosohydrazine salts were synthesized for the first time by dealkylation of 1,2-dinitroso-1,2-bis(2-cyanoethyl)hydrazine. Nitrosation of 1,2-bis(2-cyanoethyl)hydrazine yields 1-nitroso- and 1,2-dinitroso-1,2-bis(2-cyanoethyl) hydrazines. Decyanoethylation of 1-nitroso-1,2-bis(2-cyanoethyl)hydrazine results in the formation of sodium azide and disodium dinitrosohydrazinate [553].

It remains to be seen whether an ammonium salt of this acid can be synthesized. The dinitramide salt of hydrazine is described in *Encyclopedia of Oxidizers*, chapter “Hydrazinium Salts.” The dinitramide salt of hydroxylamine is described in *Encyclopedia of Oxidizers*, chapter “Hydroxylammonium Salts.”

11.7 Other Organic Nitramine Compounds

A classical metathetical reaction for the synthesis of alkyl dinitramines would be the reaction of silver dinitramide with an alkyl iodide, precipitating the insoluble silver iodide. Silver dinitramide reacts with alkyl iodides to form *N*-alkyl-*N,N*-dinitroamines [554, 555]:

Methyliodide does not react with $\text{KN}(\text{NO}_2)_2$ in acetonitrile at 253 K, but $\text{AgN}(\text{NO}_2)_2$ reacts with CH_3I within several days to form methyldinitroamine:

Reaction with $\text{C}_2\text{H}_5\text{I}$ gave a mixture of *N*-alkylated and *O*-alkylated products.

The synthesis of monoalkyl-*N,N*-dinitramines from isocyanates as a step for preparation of dinitramide salts was described in Section 2.2.

11.8 Alkyl Dinitramides as Intermediates in the Synthesis of Inorganic Dinitramides

The C—N bond in alkyl dinitramides is easily split by hydrolysis with strong alkali hydroxide, yielding the corresponding alkali dinitramide salts. The alkyl dinitramides can be isolated as intermediates, can be purified, or can be hydrolyzed without intermediate purification if dinitramide salts are the desired product. In addition to being useful as intermediates in the production of ADN or KDN, alkyl dinitramides would make good monopropellants similar to nitroalkanes.

11.8.1 Synthesis of Alkyl Dinitramides (=Alkyl *N,N*-Dinitramines)

Alkyl *N,N*-dinitramines do not belong in this section on inorganic dinitramides, but there is some information here because of their role as intermediates in the synthesis of inorganic dinitramide salts. The main section on alkyl *N,N*-dinitramines is in *Encyclopedia of Liquid Fuels*, chapter “Nitramines.” Alkyl *N,N*-dinitramines were being synthesized long before their potential use as intermediates in the production of ADN became known [69].

Alkyl *N,N*-dinitramines can be obtained by the direct nitration of the corresponding alkyl isocyanates with $\text{NO}_2\text{BF}_4/\text{HNO}_3$. If alkali metal dinitramide salts are already available by synthesis via a different route, they can be converted into alkyl dinitramines by alkylation methods. For instance, cesium dinitramide can be converted into the alkyl dinitramine by reaction with the corresponding alkyl triflates. The product yield is 40%.

Alkylation of dinitramidic acid with diazomethane in ether gives methyl dinitramine in a 30% yield.

12 Other Oxidizing Ammonium Salts

12.1 Ammonium Nitroformate

Ammonium nitroformate, $\text{NH}_4\text{C}(\text{NO}_2)_3$, ANF, CAS RN [17181-40-7] is a potential rocket propellant oxidizer, but it has received only a fraction of the attention devoted to its hydronitrogen analog, hydrazinium nitroformate. The section on hydrazinium nitroformate in *Encyclopedia of Oxidizers*, chapter “Hydrazinium Salts,” would have also been a good location for discussion of ammonium nitroformate, but for now, ammonium nitroformate, although it has some commonalities with HNF, is discussed here, immediately following sections on ADN and other dinitramide salts. This was done in order to keep the ammonium salts together, giving sorting by cations priority over sorting by anions. Ammonium nitroformate is an intermediate product of HNF decomposition and may accumulate on the surface of burning HNF pellets. Ammonium nitroformate contains the nitro groups in the anion attached to nitrogen instead of carbon, so the two salts, ADN and ANF, have some similarity. There is a potential for confusion because the name “ammonium nitroformate” has also been used for the ammonium salt of nitroformic acid, O_2NCOOH [556]. The salt $\text{O}_2\text{NCOONH}_4$ should have been called “ammonium nitroformiate”.

12.1.1 Preparation of Ammonium Nitroformate

Similar to methods used for preparation of HNF, ammonium nitroformate can be prepared by direct neutralization of nitroform with ammonia, preferably in non-aqueous solvents where the salt will precipitate and can be separated from unreacted nitroform and solvents.

12.1.2 Physical Properties of Ammonium Nitroformate

Ammonium nitroformate melts at 389 K (116 °C) with incipient decomposition.

12.1.2.1 IR and Raman Spectra of Ammonium Nitroformate

The wave numbers of absorption and fluorescence peaks in IR and Raman spectra of solid ammonium nitroformate are summarized in Table 42.

Table 42: IR and Raman spectra of solid ammonium nitroformate.

IR spectra Wavenumber ν , cm^{-1}	Raman spectra Wavenumber ν , cm^{-1}
3222 (m), 1681 (w), 1533 (m), 1460 (m), 1415 (s), 1375 (s), 1247 (s), 1147 (s), 1006 (m), 926 (m), 869 (m), 823 (w), 788 (s), 735 (s), 689 (m)	3172 (4), 2986 (7), 1610 (7), 1535 (6), 1515 (6), 1475 (10), 1380 (43), 1349 (19), 1310 (28), 1273 (72), 1225 (39), 1156 (36), 1138 (25), 871 (100), 859 (35), 791 (12), 727 (10), 466 (24), 443 (18), 415 (20), 396 (16), 375 (21), 275 (23)

Data source: [557]

12.1.2.2 Molecular Structure of Ammonium Nitroformate

The molecular structure of ammonium nitroformate is illustrated in Figure 78.

Figure 78: Molecular structure of ammonium nitroformate

12.1.2.3 Crystal Structure of Ammonium Nitroformate

Ammonium nitroformate crystallizes in the chiral tetragonal space group $P4_12_12$ (No. 92) with four formula units per unit cell [557]. The X-ray density of the crystals is 1.910 g/cm^3 .

12.1.2.4 Thermodynamic Properties of Ammonium Nitroformate

The heats of combustion of the ammonium salt of trinitromethane (**I**) (ammonium nitroformate) and the ammonium salt of 1,1-dinitropropane (**II**) were determined in a semi-microcalorimeter [558]. The heats of combustion were 1108.6 ± 1.3 and $3434.2 \pm 2.2\text{ cal/g}$ for **I** and **II**, respectively. From these values one can derive the standard enthalpies of formation (at 101 kPa and 298 K): $\Delta H^\circ_f = -47.3 \pm 0.2\text{ kcal/mol}$ and $\Delta H^\circ_f = +71.7 \pm 0.3\text{ kcal/mol}$ for **I** and **II**, respectively. On the basis of these values of ΔH°_f and data on the enthalpies of formation of $\text{HC(NO}_2)_3$, $\text{EtCH(NO}_2)_2$, and NH_3 taken from the literature, the energy of the salt bond between the nitro compound and NH_3 was estimated as 24.8 ± 0.7 and $19.9 \pm 0.6\text{ kcal/mol}$ for **I** and **II**, respectively.

Koroban et al. [559] and Williams and Brill [560] identified ANF as a product of HNF decomposition. The enthalpy of ANF dissociation, 164.77 kJ/mol (39.38 kcal/mol), is less than that of HNF and agreed closely with the experimental value.

The energies and heats of formation for ANF, HNF, and several organic nitroformate salts were calculated at the Møller-Plesset 2 (MP2) level of theory using an aug-cc-pVDZ basis set (Table 43; [557]). The values for the heat of formation obtained from these calculations were similar to, but different from, the previously reported experimental values for ANF ($-47.3 \pm 0.2\text{ kcal/mol}$) [558] and HNF ($-18.4 \pm 0.3\text{ kcal/mol}$).

Table 43: Calculated energies and heats of formation of solid ANF and solid HNF.

Compound	<i>M</i>	ρ , g/cm ³ , XRD	ΔH_L	ΔU_L	ΔH°_f	ΔU_f^0
ANF	168.10	1.910	132.4	131.2	-35.9	-792
HNF	183.09	1.938	130.0	128.8	+0.8	+125.7
		1.930	129.8	128.6	+1.0	
		1.890	129.1	127.9	+1.7	
		1.860	128.5	127.3	+2.3

ΔU_L lattice energy, kcal/mol

ΔH°_f enthalpy of formation at 298 K, kcal/mol

ΔU_f^0 energy of formation, kcal/mol

12.1.3 Thermal Stability and Decomposition of Ammonium Nitroformate

Ammonium nitroformate, ANF, CAS RN [17181-40-7], is an intermediate product of HNF decomposition and may accumulate on the surface of burning HNF pellets [561]. The kinetics of thermal decomposition of ANF and HNF share some common intermediates and pathways and are very similar. The primary reactions of the thermal decomposition of HNF as well as ANF were investigated theoretically using the G3 multilevel procedure [562]. Calculations were done for the reactions in the gas phase and in the melt and showed that the influence of the melt on the reaction barriers involves the solvation free energies. The most energetically favorable structures of HNF and ANF free molecules in the gas phase are H-bonded complexes. In the melt, the ionic structure is lowest in free energy because of solvation effects. The primary dissociation reactions of ANF resemble those of HNF.

DSC was used to determine the thermal stability of ANF. Whereas ANF shows only one decomposition signal at 389 K (116 °C) coincident with its melting, other nitroformates showed separate melting points as well as subsequent decomposition points [557].

12.1.4 Safety Properties of Ammonium Nitroformate

The impact sensitivity of ANF is 3 J, and the friction sensitivity is 96 N, compared with 15 J and 25 N, respectively, for HNF. In the same publication, the detonation velocity and detonation pressure of ADN and several other nitroform salts were calculated [557]. The theoretical detonation velocity of ANF at its maximum density is 8532 m/s.

Dinitrogen Pentoxide

Nitrogen commonly forms several different oxides with oxygen, depending on the state of oxidation of the central atom, nitrogen. The state of oxidation of nitrogen can be +1, +2, +3, +4, +5, or +6. The correct names of the six oxides are nitrous oxide (N_2O), nitric oxide (NO), dinitrogen trioxide (N_2O_3), nitrogen dioxide (NO_2), dinitrogen tetroxide (N_2O_4), dinitrogen pentoxide (N_2O_5), and nitrogen trioxide (NO_3). This chapter deals with dinitrogen pentoxide, which is also the anhydride of nitric acid. The state of oxidation of nitrogen in dinitrogen pentoxide is the highest that can be achieved without including peroxide bonds in the molecule. Because the valency of nitrogen in covalent bonds with oxygen is at most four, the structure of dinitrogen pentoxide must be formulated with semi-polar bonds, similar to those observed in nitric acid. Nitrogen trioxide NO_3 and its dimer N_2O_6 contain peroxide $-\text{O}-\text{O}-$ linkages, but those are unstable molecules observed only as short-lived transients in reactions of other nitrogen oxides.

Nitrogen oxides had to be covered in seven chapters because a single chapter devoted to the topic would have been unwieldy and made it more difficult for readers to find information on a specific compound; in addition, such an approach would have made it difficult to arrange 30 chapters among 5 subvolumes in such a way that each subvolume was about the same size. Briefer chapters made our task much easier. The other six chapters in this series are titled "Nitrogen Oxides," "Nitrous Oxide," "Nitric Oxide," "Dinitrogen Trioxide," "Nitrogen Dioxide," and "Dinitrogen Tetroxide."

Dinitrogen pentoxide is intrinsically unstable, and its exothermic decomposition has been the subject of some fundamental kinetic studies of first-order reactions.

Dinitrogen pentoxide (which is also known as N_2O_5 , dinitrogen pentaoxide, dinitrogen(V) oxide, nitrogen pentoxide, nitric acid anhydride, nitric anhydride, nitryl nitrate, nitronium nitrate, CAS RN [10102-03-1]) forms colorless crystals that sublime readily at room temperature without melting first. It is not possible to determine a melting point at normal atmospheric sea level pressure. If dinitrogen pentoxide is heated to near the anticipated melting point, it begins to decompose and liquefies, not because it melts, but because it forms a mixture of N_2O_5 and N_2O_4 . A sample of pure N_2O_5 heated in a sealed ampule to 307 K (34 °C) will decompose within 9 min and will contain 6% N_2O_4 . The decomposition may be explosive.

Dinitrogen pentoxide has been considered as a rocket propellant in the form of an additive to N_2O_4 or HNO_3 . Dinitrogen pentoxide is widely used for organic and inorganic nitration reactions in the production of nitramine explosives and ammonium dinitramide oxidizers. This avoids the use of mixed acid ($\text{HNO}_3/\text{H}_2\text{SO}_4$) and one does not have to worry about disposal of the used nitration acid with all the sulfuric acid in it. Using dinitrogen pentoxide instead of nitrating acid is thus an environmentally friendly way of performing nitration reactions [1, 2]. Because dinitrogen pentoxide

cannot be transported commercially and cannot be stored in bulk, it must be prepared immediately prior to use at the location where the nitrations are to be performed.

Dinitrogen pentoxide is a nitrogen reservoir in polar stratospheric clouds found in Antarctica and involved with ozone depletion, creating an ozone hole. It actively interconverts with the other nitrogen oxides under the influence of intense UV irradiation. The atmospheric chemistry of N_2O_5 has been extensively investigated, and this work has contributed many publications on the properties of N_2O_5 , which may also be useful for us in evaluating it as a rocket propellant. That is the main reason that, despite its thermal instability, the properties of N_2O_5 are summarized here in sufficient detail to either reconsider it or eliminate it from further consideration as a rocket propellant. With the advent of cryogenic solid propellants, frozen N_2O_5 could be a useful oxidizer as long as it is kept cold and prevented from decomposing. Because it is difficult to characterize N_2O_5 by spectroscopic methods at room temperature, freezing N_2O_5 or trapping it in a matrix of frozen argon has been standard practice for safe handling of this material. Similarly, frozen N_2O_5 could be used as a rocket propellant. It may be asserted that, at the very least, the elements that go into making N_2O_5 are in ample supply from ambient air.

1 Production of Dinitrogen Pentoxide

Dinitrogen pentoxide was first prepared by the action of dry chlorine on silver nitrate, but it is more easily made by the action of phosphoric acid anhydride (phosphorus pentoxide) on nitric acid [3, 4]. Dinitrogen pentoxide can also be produced by the ozonization of dinitrogen tetroxide or by electrochemical oxidation of N_2O_4 or HNO_3 [5].

Dinitrogen pentoxide is thermally unstable, and even at 273 K (0°C) its half-life time with respect to decomposition is only 245 h. Because of its thermal instability and high melting point, it cannot be used as a rocket propellant at room temperature. However, attempts have been made to mix dinitrogen pentoxide with other oxidizers with the aim of lowering the melting point or to improve the oxygen content of other oxidizers.

1.1 Production of Dinitrogen Pentoxide by Reaction with Ozone

Methods for N_2O_5 preparation on a laboratory scale by gas phase oxidation of N_2O_4 by ozone have been described in the literature [6, 7]. The apparatus consisted of a reaction chamber, where $\text{NO}_2/\text{N}_2\text{O}_4$ in a stream of oxygen was mixed with a stream of ozone (ca. 10%) in oxygen and the product, N_2O_5 , was trapped out as a solid in a chilled receptacle (P_2O_5 desiccant tubes were optional and for larger-scale synthesis were not found to be necessary). Also, trapping efficiency may be improved by adding extra traps. The N_2O_5 thus prepared must be stored in weighed tubes or flasks in the dark

at or below 213 K (-60°C) before use. Amounts of N_2O_5 in excess of 100 g/day may be prepared using this apparatus. Another method describes a process yielding 50 g N_2O_5 per batch [8].

The reaction of gaseous N_2O_4 with ozonized oxygen in a 1:2 molar ratio gave a 99.3% yield of N_2O_5 [9]. In reaction with ozone of solid N_2O_5 at 195 K (-78°C) or N_2O_5 dissolved in CCl_4 at 263 K (-10°C), the composition of N_2O_5 remained unaltered. The solubility of N_2O_5 in CCl_4 in the range 263 to 292 K (-10 to $+19^{\circ}\text{C}$) increased with temperature and reached 45.5% at 292 K (19°C).

Ab initio calculations using several different quantum chemical models have been made on all four reactions in which mononitrogen oxides react with ozone to generate higher oxidation states of nitrogen, culminating in N_2O_5 [10]. The relative reaction energies were determined, and all four reactions were found to be exothermic. Potential energy surfaces of the $\text{O}_3\text{-NO}$ and $\text{O}_3\text{-NO}_2$ reactant pairs were modeled using several methods, and the presence of a transition state was indicated in most of the models. For the $\text{O}_3\text{-NO}$ reaction there was reasonably good correlation with the experimental Arrhenius activation energy of 5 kJ/mol (1.2 kcal/mol). However, for the $\text{O}_3\text{-NO}_2$ reaction the calculated activation energy was four times higher than the experimental Arrhenius activation energy of 9.2 kJ/mol (2.2 kcal/mol). It does not appear to be a safe process to conduct the reaction of N_2O_4 with O_3 in an organic solvent, as suggested by some patents [11].

1.1.1 Production of Dinitrogen Pentoxide by Electrolysis

Dinitrogen pentoxide can be prepared by the electrolysis of concentrated nitric acid [12, 13]. The N_2O_5 thus prepared can be separated from its solution in nitric acid by cooling the acid solution to less than 265 K (8°C) until an N_2O_5 solvate precipitates from the solution [14].

Dinitrogen pentoxide can also be prepared by an electro-oxidation method using N_2O_4 and HNO_3 (RFNA) as raw materials [15]. The two electrochemical synthesis methods for the production of N_2O_5 by the oxidation of N_2O_4 and by the dehydration of HNO_3 were compared in terms of the current efficiency, specific energy, current density, and chemical yield of the electrolytic process [16]. The type of cell membrane and the electrode affect the current efficiency and the specific energy of the electrolysis.

Different porous polytetrafluoroethylene (PTFE) membranes were tested as the separators in the electrochemical synthesis of N_2O_5 by the oxidation of N_2O_4 in nitric acid and the effects of hydrophilicity and of hydrophobicity of the membrane on the electrolysis were studied [17]. The transport of N_2O_4 and water from catholyte to anolyte through a membrane occurred in the electrolysis, especially at the end of the electrolytic process. The water transport had much more of an effect on the electrolysis than the N_2O_4 transport. The hydrophobic PTFE membranes gave better performance with respect to the control of water transport from catholyte to anolyte than the hydrophilic ones gave. Hydrophobicity can increase the chemical yield of N_2O_5 . All the hydrophobic PTFE membranes with low resistance operated with a specific energy of

1.1–1.5 kWh/kg N_2O_5 . A current efficiency of 67–80% and chemical yield of 59–61% were achieved in the production of N_2O_5 .

The effects of electrolysis reaction time, current density, and reaction temperature on the preparation process were investigated [18]. The optimum anolyte with a higher mass fraction of N_2O_5 can be obtained using a reaction time of 4–5 h, a current density of 0.09–0.10 A/cm², and a reaction temperature of 273–283 K (5–10 °C).

Dinitrogen pentoxide can be prepared by the action of bromine pentafluoride or nitryl fluoride on an excess of lithium nitrate [19].

2 Physical Properties of Dinitrogen Pentoxide

The molecular mass of N_2O_5 is 108.0104 g/mol [20].

2.1 Melting Point of Dinitrogen Pentoxide

Dinitrogen pentoxide decomposes at the melting point. There are contradictory data in the literature about the melting point of dinitrogen pentoxide.

It was observed that a 5-g sample of dinitrogen pentoxide, resublimed in a current of ozone, condensed in a glass apparatus, then evacuated and sealed, showed signs of melting after 45 min at 303 K (30 °C), but it was concluded that “It is not a true melting, but a phenomenon complicated by the dissolving of dinitrogen tetroxide in the surface of the crystals.”

The most trustworthy results would be obtained by determining the melting point under an atmosphere of ozonized oxygen that retards some of the decomposition. Using this method, a melting point of 314 K (41 °C) was reported [21].

2.2 Density of Dinitrogen Pentoxide

The density of dinitrogen pentoxide is given in Table 1.

Table 1: Density of dinitrogen pentoxide.

Physical state	Temperature		Density	Literature
	°C	K	g/cm ³	
solid	–195	78	2.18	[22]
solid	–195	78	2.175	[23]
solid	16	289	1.99	—
solid	0	273	2.05	[24]
solid	20	293	1.786 ± 0.06	calculated

2.3 Vapor Pressure of Dinitrogen Pentoxide

The vapor pressure of dinitrogen pentoxide is listed in Table 2.

Table 2: Vapor pressure of dinitrogen pentoxide.

Temperature K	Vapor Pressure	
	mm Hg	kPa
243.2	2.3	0.31
246.7	3.3	0.44
252.2	6.3	0.84
262.5	18.6	2.47
273.1	50.9	6.76
273.2	51.5	6.8
281.9	111.2	14.8
283.7	132.2	17.6
285.45	157.7	21.0
288.2	196.8	26.2
290.7	240.9	32.0

Data source: [22]

The vapor pressure of dinitrogen pentoxide can be calculated from the following equation:

$$\log p_V = -\frac{3161.2}{T} + 1.75 \log T - 0.00606T + 10.771$$

where p_V is the vapor pressure (mm Hg) and T is the temperature (K).

2.4 Thermodynamic Properties of Dinitrogen Pentoxide

The thermodynamic properties of dinitrogen pentoxide are listed in Table 3.

2.4.1 Heat Capacity of Dinitrogen Pentoxide

The heat capacity of gaseous dinitrogen pentoxide as a function of temperature can be calculated from the following polynomial equation:

$$C_p^\circ = A + B \times t + C \times t^2 + D \times t^3 + \frac{E}{t^2}$$

where C_p is the heat capacity ($\text{J mol}^{-1} \text{K}^{-1}$), t is the temperature in kelvin divided by 1000, and A, B, C, D, and E are constants listed in Table 4 for two different temperature ranges. Note that N_2O_5 is unstable at temperatures above 298 K and the column for

Table 3: Thermodynamic properties of dinitrogen pentoxide.

Property	Temperature, K	Physical state	SI Units	Other units	References
Standard enthalpy of formation	298.15	gaseous	$+11.3 \pm 1.2$ kJ/mol	$+2.7 \pm 0.3$ kcal/mol	[25]
Standard enthalpy of formation	298.15	gaseous	$+11.30$ kJ/mol	$+2.7$ kcal/mol	[20]
Heat of fusion	—	solid	34.6 kJ/mol	8.280 kcal/mol	[22]
Heat of vaporization	281	liquid	56.5 kJ/mol	13.5 kcal/mol	[22]
Entropy	298	gaseous	346 ± 4 J mol ⁻¹ K ⁻¹	82.8 ± 1.0 cal mol ⁻¹ °C ⁻¹	[25]

the higher temperature range 1100–6000 K is only of academic interest. It is not very meaningful to list thermodynamic data for a compound that is unstable in the temperature range listed. It would be much more important to have accurate thermodynamic data for the liquid mixtures of dinitrogen pentoxide with dinitrogen tetroxide.

The JANAF tables give the heat capacity of gaseous N₂O₅ at 298 K as 96.303 J mol⁻¹ K⁻¹ [25].

2.4.2 Enthalpy of Formation of Dinitrogen Pentoxide

The standard enthalpy of formation of gaseous dinitrogen pentoxide at 298 K is +11.30 kJ/mol (+2.7 kcal/mol) [20]. The JANAF tables give $\Delta H_f^{298} = +11.297$ kJ/mol [25]. The enthalpy of formation of gaseous dinitrogen pentoxide as a function of temperature can be calculated from the following polynomial equation:

$$H^\circ - H^\circ_{298.15} = At + \frac{B \times t^2}{2} + \frac{C \times t^3}{3} + \frac{D \times t^4}{4} - \frac{E}{t} + F - H$$

where H is the enthalpy (kJ/mol), t is the temperature in kelvin divided by 1000, and A , B , C , D , E , and F are constants listed in Table 4 for two different temperature ranges.

The enthalpy of formation for solid N₂O₅ was determined via the reaction with H₂O(L) and was found to be -54.0 ± 2.5 kJ/mol = -12.91 ± 0.61 kcal/mol [26]. The enthalpy of sublimation was determined from the vapor pressure of N₂O₅ measured as a function of temperature at 211–273 K and was found to be 59.01 ± 0.31 kJ/mol = 14.104 ± 0.075 kcal/mol. From these data and the enthalpy of the reaction

Table 4: Thermodynamic property polynomial equation coefficients for dinitrogen pentoxide vapor.

Temperature range, K	298–800	800–6000
A	23.85152	149.4818
B	337.9894	0.154807
C	−353.4530	−0.038263
D	134.8407	0.003074
E	−0.042447	−8.093070
F	−8.123279	−57.10198
G	288.9203	490.8418
H	11.29701	11.29701

Data source: [20]

(determined from the temperature dependence of the equilibrium constant), the enthalpies of formation for $\text{N}_2\text{O}_5(\text{G})$ and $\cdot\text{NO}_3(\text{G})$ were determined as $+4.98 \pm 2.55 \text{ kJ/mol}$ ($+1.19 \pm 0.61 \text{ kcal/mol}$) and $+64.4 \pm 3.1 \text{ kJ/mol}$ ($+15.39 \pm 0.75 \text{ kcal/mol}$), respectively. The enthalpy of formation of the $\cdot\text{NO}_3$ radical was therefore found to be significantly less than the commonly accepted value.

2.4.2.1 Entropy of Dinitrogen Pentoxide

The standard entropy of formation of gaseous dinitrogen pentoxide at 298 K and 101 kPa is $346.55 \text{ J mol}^{-1} \text{ K}^{-1}$ [20]. The entropy of gaseous dinitrogen pentoxide as a function of temperature can be calculated from the following polynomial equation

$$S^\circ = A \times \ln(t) + B \times t + \frac{C \times t^2}{2} + \frac{D \times t^3}{3} - \frac{E}{2 \times t^2} + G$$

where S° is the enthalpy in $\text{J mol}^{-1} \text{ K}^{-1}$, t is the temperature in kelvin divided by 1000, and A, B, C, D, E, and G are constants listed in Table 4 for two different temperature ranges.

2.5 Molecular Structure of Dinitrogen Pentoxide

It is unfortunate that dinitrogen pentoxide is so unstable that it cannot be used as a rocket propellant. Its oxygen content and energy content would be superior to that of the widely used dinitrogen tetroxide. We are exploring the molecular structure of dinitrogen pentoxide here in the hope of better understanding the causes of its instability and in the hope of finding other nitrogen oxides that may be useful as oxidizers. After all, cryogenic rocket propellants open up avenues to rocket propellants that had previously been rejected from further consideration because they are unstable at room temperature.

Gaseous N_2O_5 consists of two $-\text{NO}_2$ groups bonded to a bridging O atom to form a non-linear $\text{N}-\text{O}-\text{N}$ moiety. The $-\text{NO}_2$ groups undergo slightly hindered internal rotation around the bonds to the bridge so that instantaneous composition of the gaseous system at any time is characterized by molecules with all combinations of torsion angles.

The dinitrogen pentoxide molecule should consist of two nitro groups attached to a central oxygen. If this were a linear, symmetrical molecule with a 180° valence angle for the central oxygen, this structure would have zero dipole moment. In contrast to that, the considerable moment of 1.39 D obtained from microwave measurements showed this to be impossible. Evidently, the molecule is bent and a very rough value of the oxygen valence angle (approx. 140°) may be calculated from the group and bond moments involved [27].

The structure of dinitrogen pentoxide has been investigated in the gas phase at a temperature of 262 K (-11°C) [28]. This study assumed that the structure of the $\text{O}-\text{NO}_2$ groups was invariant to torsion angle and that these groups had C_{2v} symmetry. The molecule consists of two $-\text{NO}_2$ groups joined to a fifth oxygen atom by non-collinear bonds (Figure 1). On each side of the molecule, one of the $\text{N}=\text{O}$ bonds is actually a semipolar bond, but the drawing software does not have the ability to display semipolar bonds.

Figure 1: Molecular structure of dinitrogen pentoxide.

The $-\text{NO}_2$ groups are undergoing large-amplitude torsional motion about a point of minimum energy corresponding to C_2 symmetry for molecules at dihedral angles τ_1 and τ_2 between these groups and an $\text{N}-\text{O}-\text{N}$ plane of about 30° each. The torsional motion was modeled by a potential representing a competition between bonding forces tending to stabilize the planar conformation and repulsive forces between oxygen atoms on different $-\text{NO}_2$ groups tending to destabilize it. The results suggested the motions of the $-\text{NO}_2$ groups are loosely coupled in such a way that one torsion angle tends to increase from the minimum energy point as the other decreases. The bond distances and angles with estimated 2σ uncertainties are $r(\text{N}=\text{O})$ 1.188(2) Å, $r(\text{N}-\text{O})$ 1.498(4) Å, $\angle\text{O}=\text{N}=\text{O}$ $133.2(6)^\circ$, $\angle\text{N}-\text{O}-\text{N}$ $111.8(16)^\circ$, and $\langle\tau_1 = \tau_2$ 30° at potential energy minimum.

In the solid phase, N_2O_5 has the ionic structure $[\text{NO}_2^+][\text{NO}_3^-]$. Based on X-ray diffraction (XRD) analysis, the crystal structure of solid N_2O_5 at 105 K (-168°C) is pseu-

dohexagonal, space group $P6_3/mmc$, with $a = 5.4019(9)$ and $c = 6.5268(13)$ Å; $d_c = 2.175 \text{ g/cm}^3$ for $Z = 2$. The structures were solved by direct methods and refined by least-squares to $R = 0.028$ [29]. An earlier XRD structural analysis of crystalline N_2O_5 at 213 K had resulted in $a = 5.41$ Å, $c = 6.57$ Å [30]. See also [31, 32].

2.5.1 Computational Chemistry of Molecular Structure of Dinitrogen Pentoxide

Ab initio MO calculations to determine the minimum-energy structure of N_2O_5 showed that N_2O_5 had an anhydride-type structure with its nitro groups rotated $\sim 42^\circ$ out of the central N—O—N plane in a conrotatory fashion [33].

Several conformers have been considered for N_2O_5 , and *ab initio* calculations on these conformers identified three minimum-energy structures, namely, planar, perpendicular, and fully optimized structure [34]. The global minimum energy was characterized by vibrational frequency analysis. The calculations indicated that the fully optimized structure had a C_2 symmetry with its nitro groups rotated $\sim 35^\circ$ from the central N—O—N plane in a conrotatory manner. The *ab initio* frequencies of N_2O_5 were compared to those determined by experiment or density functional theory (DFT) methods.

Other potential, speculative isomer structures for N_2O_5 are shown in the following graphs (note that some of the N=O bonds are semipolar bonds):

Nitro nitroso peroxide
CAS RN [919401-11-9]

2,4,5-Trioxo-1,3-diazabicyclo[1.1.1]pentane, 1,3-dioxide
CAS RN [224950-19-0]

The N_2O_5 molecule has been investigated in terms of a more realistic model in which the symmetry restriction was relaxed, account was taken of structural changes in the $-\text{NO}_2$ groups with torsion angle as predicted by *ab initio* theory, and a more convenient form of the torsional potential was assumed [35]. The most stable conformation has C_2 symmetry with torsion angles τ_1 , defined as $\angle(\text{N}-\text{O}-\text{N}=\text{O}_4)$, equal to τ_2 , defined as $\angle(\text{N}-\text{O}-\text{N}=\text{O}_6)$, equal to 33.7° ; because of the broad potential minimum in this region, the uncertainty in these angles was difficult to estimate, but it was esti-

mated at 3–4°. The revised results for the bond lengths and bond angles for the most stable conformation were $r_g(\text{N}-\text{O}) = 1.505(4) \text{ \AA}$, $r_g(\text{N}=\text{O}) = 1.188(2) \text{ \AA}$, $\angle(\text{N}-\text{O}-\text{N}) = 112.3(17)^\circ$, $\angle(\text{O}=\text{N}=\text{O}) = 134.2(4)^\circ$, and $\angle(\text{O}-\text{N}=\text{O}) = 112.8(2)^\circ$. The difference between the symmetry-non-equivalent $\text{O}-\text{N}=\text{O}$ angles was estimated to be ca. 6.7°, with the larger angle positioning the two $\text{N}=\text{O}$ bonds on different $-\text{NO}_2$ groups nearest each other.

DFT quantum-chemical calculations have shown that the molecular structures of N_2O_5 with C_s and C_2 symmetries are energetically equivalent [36]. It follows from calculations of the vibrational frequencies that both structures are characterized by potential energy minima and correspond to stationary states of the N_2O_5 molecule. It has been proposed, on the basis of a comparison of the calculated and experimental vibrational spectra of N_2O_5 , that dinitrogen pentoxide exists in the gas phase as an equimolecular mixture of N_2O_5 molecules with C_s and C_2 symmetry, while in the solid phase it is characterized by the C_2 molecular structure. See also [37].

2.6 Optical Properties of Dinitrogen Pentoxide

Because of the involvement of dinitrogen pentoxide in atmospheric chemistry, in particular chemistry taking place in the ozone layer high above the breathable atmosphere, its absorption spectra have been thoroughly investigated. Having accurate spectra of N_2O_5 by itself should help in the identification of other nitrogen oxides potentially formed at the same time that could be used as rocket propellants.

2.6.1 Ultraviolet Spectra of Dinitrogen Pentoxide

Because reactions with N_2O_5 play a role in atmospheric chemistry, UV absorption cross sections for N_2O_5 vapor were measured at wavelengths between 200 and 380 nm and temperatures between 223 and 300 K [38]. The absorption spectrum above 290 nm showed a pronounced temperature dependence.

The spectrum and photoabsorption cross sections of N_2O_5 at 195 K between 150 and 240 nm consisted of a broad intense band with a maximum at 160 nm [39]. The lack of sharp features indicated that excitation of N_2O_5 resulted in dissociation over the entire spectral range studied. At wavelengths >200 nm, the measured absorptions were up to 30% smaller than older data reported in the literature but were in generally good agreement with more recent measurements. Below 200 nm, there were no reported data in the literature.

Dinitrogen pentoxide has UV absorptions at 204, 213, 258 nm ($\pi \rightarrow \pi^*$) 378 and 384 nm ($n \rightarrow \pi^*$) [8]. See also [40].

2.6.2 Infrared Spectra of Dinitrogen Pentoxide

2.6.2.1 Infrared Spectra of Gaseous Dinitrogen Pentoxide

The IR spectrum of N_2O_5 in the gas phase is remarkably similar to that of the equilibrium mixture of $\text{NO}_2/\text{N}_2\text{O}_4$. Like planar N_2O_4 , covalent N_2O_5 showed all the bands characteristic of the nitro group, namely, an asymmetric stretch (at 1720 cm^{-1}), a symmetric stretch (at 1240 cm^{-1}), and an ONO bend (at 730 cm^{-1}), in full agreement with the structure usually postulated for this molecule of two nitro groups linked (non-linearly) through an oxygen atom.

Because N_2O_5 has been detected in the upper atmosphere, where it plays a role in air pollution and ozone layer depletion, its spectral properties have been extensively investigated and methods for the remote analysis of traces of N_2O_5 in the atmosphere have been developed. Daily, seasonal, and vertical profiles of changes in the N_2O_5 concentration in the atmosphere have been developed using a variety of remote sensing techniques.

In the mid-IR region, absorptions were observed at 1720 , 1246 , 743 , and 557 cm^{-1} [41]. These absorptions can be used for the stratospheric detection of N_2O_5 .

The absorption of gaseous dinitrogen pentoxide in the 8.1 - and $5.7\text{-}\mu\text{m}$ spectral regions was measured with a fast-scanning Fourier transform infrared (FTIR) spectrometer with a flow-through system in order to maintain pure, fresh N_2O_5 samples in the absorption cell [42]. The amount of inevitable impurities, such as NO_2 and HNO_3 , in the cell was evaluated from the measurement of their individual absorptions, and the results were used to determine the partial pressure of N_2O_5 . The total intensities of the N_2O_5 bands located at 8.1 and $5.7\text{ }\mu\text{m}$ were as follows: $I_{\text{N}_2\text{O}_5}(8.1\text{ }\mu\text{m}) = 1508 \pm 100\text{ cm}^{-1}\text{ atm}^{-1}\text{ cm}^{-1}$ and $I_{\text{N}_2\text{O}_5}(5.7\text{ }\mu\text{m}) = 3580 \pm 167\text{ cm}^{-1}\text{ atm}^{-1}\text{ cm}^{-1}$ at 296 K .

Absorption cross sections for three strong IR bands of N_2O_5 were measured as a function of temperature at 233 – 350 K [43]. The Beer-Lambert linearity of signal strength vs. concentration was confirmed.

The far-IR spectrum of N_2O_5 at room temperature in the gas phase showed a broad, weak feature with its maximum near 50 cm^{-1} , and its intensity was 1.20 (10%) of that of the band at 350 cm^{-1} [44]. The latter band, in turn, had a band intensity of around 0.33 of that of the band at 1250 cm^{-1} .

Laboratory measurements of the $\nu_{1,2}$ absorption band of gaseous N_2O_5 were made using FTIR spectroscopy at seven different temperatures between 233 and 293 K [45]. Integrated band strengths and absorbance cross sections per molecule showed no significant temperature dependence. The average values were $S_{\text{int}} = (4.09 \pm 0.17) \times 10^{-17}\text{ cm}^2/\text{mol}$ and $\sigma_{\text{peak}} = (1.90 \pm 0.08) \times 10^{-18}\text{ cm}^2/\text{mol}$.

IR absorptions of dinitrogen pentoxide vapor reported at 1428 , 1266 , 1249 , 1206 , 1044 , 822 , 750 , 546 , and 454 cm^{-1} from reference [8] do not agree with absorptions listed at the NIST Chemistry WebBook site [46]. See also [47, 48].

2.6.2.2 Infrared Spectra of Frozen or Matrix-Isolated Dinitrogen Pentoxide

At liquid nitrogen temperatures, pure dinitrogen pentoxide forms an ionic $\text{NO}_2^+\text{NO}_3^-$ lattice, as indicated by its IR spectra, but at liquid helium temperatures, deposition was only in the easily recognized covalent form [49].

FTIR spectra of the covalent dinitrogen pentoxide molecule isolated in a solid Ar matrix at 10 K showed that frequencies in the $200\text{--}4000\text{ cm}^{-1}$ region were in close agreement with previously reported gas phase values [50]. An accurate and sophisticated *ab initio* study showed that the stable equilibrium structure, C_2 symmetry, was in agreement with the structure previously determined by electron diffraction data.

2.6.3 Raman Spectra of Dinitrogen Pentoxide

A Raman spectral study of solutions of N_2O_4 and N_2O_5 in anhydrous and aqueous HNO_3 provided a more detailed knowledge of the species present in these solutions and assessed the applicability of Raman spectroscopy as an analytical measurement technique [51]. The nitronium cation, NO_2^+ , is the dominant species in solutions of N_2O_5 in anhydrous HNO_3 . A new band was discovered in the spectra of concentrated solutions of N_2O_5 . This weak band, which may be the same as a band found in the spectra of solids containing the nitronium cation, was attributed to a second vibrational mode of the molecule. This indicated a non-linear conformation of the NO_2^+ ion and suggested that it is strongly associated with other species in the solution. The Raman data indicated that N_2O_5 in HNO_3 is completely ionized at concentrations up to at least 3.0 mol/L (21 mass-%).

Nitrosonium nitrate, NO^+NO_3^- , and dinitrogen pentoxide (nitronium nitrate), $\text{NO}_2^+\text{NO}_3^-$, ionic crystals were synthesized by laser heating of a condensed oxygen-rich O_2/N_2 mixture compressed to extremely high pressures, up to 40 GPa, in a diamond anvil cell [52]. High-pressure/high-temperature Raman and XRD studies of high-pressure samples revealed a transformation of NO^+NO_3^- to $\text{NO}_2^+\text{NO}_3^-$ crystals at temperatures above ambient and pressures below 9 GPa. High-pressure experiments revealed previously unreported bands in the Raman spectra of NO^+NO_3^- and $\text{NO}_2^+\text{NO}_3^-$ ionic crystals. There may be a rotational disorder in solid NO^+NO_3^- and $\text{NO}_2^+\text{NO}_3^-$. See also [19].

2.6.4 Microwave Spectra of Dinitrogen Pentoxide

Nine molecular constants were determined from the preliminary assignments of microwave absorptions of N_2O_5 , but they did not allow for reproducing all the observed microwave transitions to their experimental accuracy [53].

The rotational spectrum of expanding N_2O_5 gas jets was studied between 8 and 25 GHz at a rotational temperature of around 2.5 K using a pulsed-molecular-beam Fourier-transform microwave spectrometer [54]. Two weak b-dipole spectra were observed for two internal-rotor states of the molecule, with each spectrum poorly characterized by an asymmetrical-rotor Hamiltonian. Analysis of the ^{14}N nuclear hyperfine

structure demonstrated that the two N nuclei occupy either structurally equivalent positions or are interchanging non-equivalent structural positions via tunneling or internal rotation at a rate larger than around 1 MHz. The spectrum was assigned to the symmetrical and anti-symmetrical tunneling states of a C_2 symmetry N_2O_5 with internal-rotation tunneling of the two NO_2 groups via a geared rotation about their respective C_2 axes. Model dynamical calculations suggested that the internal-rotation potential was significantly more isotropic than implied by electron-diffraction analysis.

Rotational spectra of b-type subbands of N_2O_5 for both internal-rotor states were recorded using a pulsed-nozzle Fourier-transform microwave spectrometer [55]. The measurements extended previous results on N_2O_5 , which were confined to the rR0, rR1, rQ1, and rP1 b-type subbands due to limitations in the frequency coverage of the instrument. The measurements provided new energy-level differences, which gave a nearly complete picture of the $K = 0, 1$, and 2 energy levels. The measurements also supported N_2O_5 as a C_2 symmetry molecule with facile geared internal rotation of two equivalent NO_2 groups. The IR spectra of the 1246 cm^{-1} , $\nu_{1,2}$, N—O stretching fundamental band of N_2O_5 were also recorded and revealed a complex resolved rotational structure, which remained unanalyzed.

2.6.5 Photoelectron (XPS) Spectroscopic Studies of Dinitrogen Pentoxide

He I photoelectron spectra for dinitrogen tetroxide and dinitrogen pentoxide obtained by rapid expansion of the vapor were compared with Gaussian *ab initio* molecular orbital calculations and with the spectra of the dissociated species, also in relation to nitric acid [56]. Several possible geometrical structures were considered in the case of dinitrogen pentoxide. It was shown that a planar form with an N—O—N angle on the order of 120° is most consistent with the photoelectron spectra results.

3 Chemical Properties of Dinitrogen Pentoxide

Dinitrogen pentoxide is soluble in bromine, dinitrogen tetroxide, tetrachloromethane, chloroform, ethylene chloride, ethylidene chloride, pentachloroethane, or nitromethane without chemical reaction. Nitric acid at room temperature dissolves up to 90 mass-% N_2O_5 , which makes it a powerful nitrating agent for the synthesis of organic high-energy compounds. Nitromethane at 288 K (15°C) dissolves 4.38 Mol N_2O_5 /L. See also [57].

3.1 Reactions of Dinitrogen Pentoxide

3.1.1 Reactions of Dinitrogen Pentoxide with Inorganic Substances

Dinitrogen pentoxide reacts with water under strong heat evolution to form nitric acid. In spite of this reactivity, it is surprising to learn that frozen N_2O_5 and ice crystals co-exist in the high atmosphere, where they do not immediately react with each other. Dry ammonia will not ignite spontaneously with N_2O_5 .

3.1.2 Reactions of Dinitrogen Pentoxide with Organic Substances

Most organic compounds undergo nitration, and not all ignite spontaneously when they first come in contact with N_2O_5 . Some inert organic solvents have been patented as solvent media for the production of N_2O_5 from N_2O_4 and ozone. Reactions of N_2O_5 with alkanes lead to mixtures of nitroalkanes. Nitroalkanes can be prepared by the direct nitration of aliphatic or alicyclic hydrocarbons with nitric acid, nitrogen dioxide, or dinitrogen pentoxide. Two complementary but essentially different reaction systems are available, namely, N_2O_5 in nitric acid and N_2O_5 in organic inert solvents. The former system possesses strength similar to that of mixed acid (nitric/sulfuric acid) systems but has advantages such as ease of generation of the nitration reagent by electrolysis and more easily recyclable reaction media. The latter system permits the generation of polynitrated species directly without the formation of acidic byproducts, notably by a new type of nitration reaction, addition nitration, where reactions with strained-ring heterocyclic compounds yield a wide variety of products [58–61] in the vapor phase at elevated temperatures, but this is a very hazardous operation since one is essentially feeding rocket propellants into a reactor just short of ignition or explosion conditions. N_2O_5 produced *in situ* by the electrolysis of HNO_3 has become an important nitration agent in the production of explosives such as HMX and RDX. For this application, N_2O_5 does not have to be isolated in the pure state, but it can be used as a solution in nitric acid, the same nitric acid used as the electrolyte in electrosynthesis apparatus. The use of dinitrogen pentoxide instead of a mixture of nitric acid and concentrated sulfuric acid as a nitrating agent results in an environmentally more friendly production process because it is not necessary to dispose of the spent nitrating acid that contains sulfuric acid. Cyclotetramethylenehexamine can be converted to RDX in a one-step reaction with N_2O_5 as the nitrating agent [62]. Nitrations with N_2O_5 give clean products with fewer byproducts [63].

Both N_2O_5 and HNO_3 are soluble in liquid CO_2 (not necessarily under supercritical conditions because supercritical CO_2 dissolves just about everything) and can be used in this inert solvent to safely nitrate many organic compounds in the preparation of energetic materials [64].

3.2 Thermal Stability of Dinitrogen Pentoxide

3.2.1 Dissociation of Dinitrogen Pentoxide

Dinitrogen pentoxide can dissociate and convert to the ionic form of nitryl nitrate, which then dissociates in a heterolytic reaction into nitronium and nitrate ions [65]:

A third-law method was used to assess the authenticity and accuracy of the available equilibrium constants and thermodynamic properties of the thermal dissociation of N_2O_5 in accordance with

Recommendations were made for the heats of formation and dissociation and for identifying the need for further determination of the basic property values of this compound [66].

Equilibrium geometries and transition states for the equilibrium

and for the reaction

have been predicted using DFT methods and *ab initio* calculations [67]. The optimized geometries for N_2O_5 were in good agreement with experiments and previous calculations reported in the literature. A transition state for the decomposition of N_2O_5 has been located. Reaction (R-2) proceeds via a complex mechanism. The first step is the formation of a peroxy intermediate $\text{ONO}\cdots\text{ONO}_2$ that can rearrange via a high lying intermediate to $\text{ON}(\text{O}_2)\cdots\text{ONO}$, which can then yield $\text{NO}_2 + \text{NO} + \text{O}_2$.

3.2.2 Thermal Decomposition of Dinitrogen Pentoxide

The decomposition of N_2O_5 was studied by measuring the pressure rise in an all-glass apparatus in the temperature range from 298 to 328 K (25 to 55 °C), and it was then that it was first recognized that the decomposition reaction is a monomolecular reaction [68–70]. The experiments were conducted in a blackened apparatus to exclude any light since it was known that N_2O_5 will decompose faster through photolysis. The surface: volume ratio of several different apparatus used had no effect on the rate of decomposition. The pressure measurements were corrected for the equilibrium dissociation of N_2O_4 , which resulted in additional pressure that was subtracted from the total pressure.

The thermal decomposition of N_2O_5 can be retarded somewhat in the presence of ozone [71, 72], but not in the presence of excess oxygen or dinitrogen tetroxide [73].

3.2.2.1 Kinetics of Dinitrogen Pentoxide Decomposition

The decomposition of dinitrogen pentoxide is a first-order reaction and has served as a model substance in the derivation of kinetic equations to characterize such reactions. Dinitrogen pentoxide decomposes irreversibly similar to radioactive decay in a monomolecular first-order reaction that has often been used as a model reaction for fundamental kinetic studies [74]:

The half-life at 273 K (0 °C) is 244.8 h, at 288 K (15 °C) it is 18.5 h, and at 293 K (20 °C) it is only 9.9 h. The rate of decomposition cannot be influenced by lowering the pressure, by dilution with inert gases, or by dissolving it in inert solvents [75]. The decomposition of N_2O_5 proceeds at the same rate down to pressures of 0.06 mm Hg [76–79]. This rapid decomposition makes it very improbable that dinitrogen pentoxide can be stored long enough to be used as a rocket propellant.

In some solvents, the rates of decomposition and their temperature coefficients behave quite abnormally [80]. The rate of decomposition is greatly accelerated by illumination, so thermal decomposition becomes photolysis. In the presence of ozone, N_2O_5 decomposes more slowly. On the other hand, the addition of N_2O_4 shortens the half-life. The decomposition of N_2O_5 in N_2O_4 solution proceeded twice as fast as in the gas phase. Some reports have stated that samples of N_2O_5 stored at room temperature explode randomly without an identifiable cause. Most construction materials that are resistant to N_2O_4 can also be used for handling N_2O_5 .

The equilibrium constant for $\text{N}_2\text{O}_5 \rightleftharpoons \bullet\text{NO}_2 + \bullet\text{NO}_3$ has been determined through direct concentration measurements of N_2O_5 , NO_2 , and $\bullet\text{NO}_3$ in a temperature-controlled long path cell using absorption spectroscopy in the infrared and visible regions from 243 to 397 K [81]. The equilibrium constant was found to be

$$k_{1C} = 1.30 \times 10^{26} \exp(-21490/RT) \text{ molecules cm}^{-3}$$

with an estimated overall uncertainty of 30% at the 95% confidence level. This equilibrium constant at near room temperature was approximately half that of previously accepted values. Using the temperature dependence of the equilibrium constant and new data for the enthalpy of formation of gaseous N_2O_5 yielded an enthalpy of formation for $\bullet\text{NO}_3$ of $+64.4 \pm 3.1 \text{ kJ/mol}$ ($+15.39 \pm 0.75 \text{ kcal/mol}$). The temperature-dependent first-order decay rates of N_2O_5 were determined, from which a value for the product of the equilibrium constant k_{1C} and the rate constant for

was obtained for temperatures from 298 to 396 K:

$$k_1 k_2 = 1.23 \times 10^{13} \exp(-24300/RT) \text{ s}^{-1}.$$

When this was combined with the equilibrium constant, the following expression was obtained for k_2 :

$$k_2 = 9.5 \times 10^{-14} \exp(-2810/RT) \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}.$$

Qualitative valence bond considerations were used to explain how electronic reorganization could proceed for (a) the formation of N_2O_5 via the reactions

and

and (b) the thermal decomposition of N_2O_5 via the following sets of reactions:

Increased-valence structures, which possess one-electron bonds and fractional electron-pair bonds as well as so-called normal electron-pair bonds, were used to represent the electronic structures of molecules [82].

The thermal decomposition rate of the tropospheric component N_2O_5 at 101 kPa of air as a function of temperature between 314 and 348 K was investigated using pulsed laser cavity ring-down spectroscopy (CRDS) for the detection of NO_3 radicals at 662 nm [83]. The Arrhenius expression of the thermal decomposition rates determined by CRDS over the temperature range 263–348 K is

$$k = 1.36 \times 10^{15} \exp\{(-11300 \pm 200)/T\} \text{ s}^{-1}.$$

3.3 Photolysis of Dinitrogen Pentoxide

Because small amounts of dinitrogen pentoxide form in the stratosphere under the influence of ozone and ultraviolet light, the same conditions that bring about its formation are also conducive to its decomposition, most of all by photolysis [84].

Pulsed laser photolysis of N_2O_5 near 290 nm coupled with fluorescence detection (calibrated by NO_2 photolysis) showed that the $\text{O}(^3\text{P})$ quantum yield is ≤ 0.1 [85]. A pulsed laser optoacoustic technique in a flow tube was tested by the photolysis of NO_2 and then applied to the photolysis of N_2O_5 . Nitric oxide was added to react with $\bullet\text{NO}_3$ free radicals, and the resulting increase in the optoacoustic signal confirmed the presence of $\bullet\text{NO}_3$ free radicals. Based on the relative optoacoustic signals observed for NO_2 and N_2O_5 , the quantum yield for $\bullet\text{NO}_3$ production was 0.8 ± 0.2 .

The quantum yield for the production of $\bullet\text{NO}_3$ free radicals in N_2O_5 photolysis at 248 nm was measured to be near unity [86]. The concentration of $\bullet\text{NO}_3$ produced upon photolysis was measured using 662-nm laser absorption. The quantum yields for $\text{O}(^3\text{P})$ production in the photolysis of N_2O_5 at 248, 266, 287, and 289 nm were also measured using resonance fluorescence detection of $\text{O}(^3\text{P})$. The quantum yield for $\text{O}(^3\text{P})$ decreased from 0.7 at 248 nm to 0.15 at 289 nm.

A combination of matrix isolation and FTIR spectroscopy was used to investigate the low-temperature photochemistry (4.2 K) of dinitrogen pentoxide [87]. UV photolysis of the matrix isolated precursor at $\lambda > 230$ nm resulted in the photoreduction of N_2O_5 to N_2O via N_2O_3 as an intermediate. Both *asym*- and *sym*- N_2O_3 were formed in argon matrices, whereas in solid nitrogen only *asym*- N_2O_3 was produced. Little or no evidence was found for the potential formation of isomeric forms of N_2O_4 .

3.4 Analysis of Dinitrogen Pentoxide

Solutions of N_2O_5 , N_2O_4 , and HNO_3 in methylene chloride can be analyzed by IR spectroscopy [88].

4 Hazardous Properties of Dinitrogen Pentoxide

According to some reports, samples of pure N_2O_5 stored at room temperature have exploded spontaneously without an identifiable cause. The material should therefore be stored separate from all other chemicals and only in non-fragmenting, vented containers. N_2O_5 solutions in inert solvents can be stored at low temperatures in vented containers with pressure relief valves.

The vapors of subliming N_2O_5 are very toxic. They hydrolyze in the nostrils, trachea, and lungs, forming nitric acid. The vapor pressure of N_2O_5 crystals at room temperature is sufficiently high to cause serious poisoning accidents [89]. Dinitrogen pentoxide is much more poisonous than N_2O_4 . Test rats exposed to various constant concentrations in a range of 1 to 4 ppm N_2O_5 for a few hours died at any concentration higher than 2 ppm within a few hours. In a parallel test, other animals survived 8 to 20 ppm N_2O_4 without undue effects. The toxicity of N_2O_5 has been compared to that of phosgene. Dinitrogen pentoxide may form as a byproduct during the ozonization of air. Ozone made by ozonization of air is much more toxic than ozone made from a glow discharge in or UV illumination of pure oxygen.

5 Dinitrogen Pentoxide Mixtures with Other Oxidizers

It would be ideal to be able to mix N_2O_5 with other compatible oxidizers to stabilize it and widen the liquid range. The most likely candidates for such mixtures would be dinitrogen tetroxide, N_2O_4 , and the acid for which N_2O_5 is the anhydride, nitric acid HNO_3 . Unfortunately, N_2O_4 accelerates the decomposition of N_2O_5 and cannot be used as a solvent.

If one accepts the need to keep these propellants cool as a necessary evil, one can consider oxidizer mixtures containing dinitrogen pentoxide and evaluate them as rocket propellant oxidizers. What makes them attractive is the high oxygen content, high enthalpy of formation, ready availability of the constituent elements nitrogen and oxygen from ambient air, and clean combustion products (as opposed to fluorinated high-energy oxidizers). However, most experienced rocket propellant chemists scoff at the idea of using dinitrogen pentoxide and regard it as pure speculation. There have been no known applications of dinitrogen pentoxide in rocket engines. On the other hand, future use of cryopropellants where all ingredients are solid at the temperature of liquid nitrogen will enable us to use propellant ingredients previously thought to be too unstable for practical applications.

5.1 Dinitrogen Pentoxide/Nitric Acid Mixtures

Solutions of dinitrogen pentoxide in nitric acid are very useful nitrating agents and cleaner than traditional nitrating acid (a mixture of nitric acid and sulfuric acid). Electrochemical methods for the preparation of $\text{N}_2\text{O}_5/\text{HNO}_3$ mixtures have been thoroughly investigated [90–93]. Therefore, knowledge of the electrical conductivity of such mixtures is useful information (Section 5.1.5). A nitration method using an N_2O_5 /organic solvent system is a much milder and more selective nitration method, which is well suited for cases where the substrates or products are sensitive to acid or water and for regioselective O-nitration [94].

Mixtures of N_2O_5 and HNO_3 would be easier to use as a rocket propellant oxidizer than N_2O_5 by itself. They would be hypergolic with many fuels that are not reactive or less reactive with White Fuming Nitric Acid (WFNA) or Red Fuming Nitric Acid (RFNA). There are no known uses of such mixtures as rocket propellants.

5.1.1 Freezing Point of Dinitrogen Pentoxide/Nitric Acid Mixtures

The freezing point of dinitrogen pentoxide/nitric acid mixtures goes through a minimum near 23% N_2O_4 at 204 K (−69 °C) (Table 5).

The liquid-liquid and solid-liquid equilibrium phase boundaries and liquid-liquid and solid-liquid equilibrium data for the ternary $\text{N}_2\text{O}_4/\text{N}_2\text{O}_5/\text{HNO}_3$ system were measured by a cloud point method at 258.2, 265.2, 273.2, and 281.2 K [95, 96]. The criti-

Table 5: Freezing point of dinitrogen pentoxide/nitric acid mixtures.

Data source: [24]

cal points and the solubility of dinitrogen pentoxide in dinitrogen tetroxide and nitric acid, the solubility of dinitrogen tetroxide in nitric acid, and the solubility of nitric acid in dinitrogen tetroxide were also obtained separately. With an increase in temperature, the two-phase area shrank and the solubilities of dinitrogen pentoxide in dinitrogen tetroxide and nitric acid, dinitrogen tetroxide in nitric acid, and nitric acid in dinitrogen tetroxide increased, as expected. A versatile method for analyzing ternary $\text{N}_2\text{O}_4/\text{N}_2\text{O}_5/\text{HNO}_3$ mixtures was developed for the study of $\text{N}_2\text{O}_4/\text{N}_2\text{O}_5/\text{HNO}_3$ systems [97].

5.1.2 Vapor Pressure of Dinitrogen Pentoxide/Nitric Acid Mixtures

The physical properties of $\text{N}_2\text{O}_5/\text{HNO}_3$ mixtures have been well characterized. The boiling point of $\text{N}_2\text{O}_5/\text{HNO}_3$ mixtures decreased with increasing N_2O_5 concentration (Table 6). The vapor pressure of $\text{N}_2\text{O}_5/\text{HNO}_3$ mixtures at 273 K follows an additive behavior of the partial pressures [98] (Table 7).

Table 6: Boiling point of dinitrogen pentoxide/nitric acid mixtures.

Concentration of free N_2O_5	Total amount of N_2O_5 (free and in the form of HNO_3 chemically bound)	Concentration of N_2O_4 (a contaminant)	Boiling point

Data source: [24]

Evaluation of published data led to the conclusion that a heteroazeotropic equilibrium exists in the nitric acid-dinitrogen pentoxide system, and a phase diagram was constructed [99]. The heteroazeotrope contained 1–2 mass-% HNO_3 at 101 kPa (760 mm Hg) and approximately 303 K (30 °C).

5.1.3 Density of Dinitrogen Pentoxide/Nitric Acid Mixtures

The density of $\text{N}_2\text{O}_5/\text{HNO}_3$ mixtures increased steadily with an increasing concentration of N_2O_5 (Table 8) (Figure 2). The densities of $\text{N}_2\text{O}_5/\text{HNO}_3$ mixtures at 253 and 263 K (–20 and –10 °C) were measured by Taylor, Lyne, and Follows [100] as part of an electrical conductivity study experiment.

Table 8: Density of dinitrogen pentoxide/nitric acid mixtures.

Free N_2O_5 , mass-%	Total mass% N_2O_5 (free and in the form of HNO_3 chemically bound)	Mass-% N_2O_4 (a contaminant)	Density at 288 K (15 °C), g/cm ³
1.92	85.98	—	1.530
9.40	87.05	—	1.553
13.53	87.64	0.003	1.572
16.47	88.04	0.02	1.588

24.93	89.24	0.03	1.630
30.53	89.98	0.09	1.643
33.05	90.10	0.33	1.645

Data source: [24]

Figure 2: Density of dinitrogen pentoxide/nitric acid mixtures (chart created by Schmidt 2021, based on data from [101])

It was shown that the addition of ammonium nitrate confers a considerable degree of thermal stability on anhydrous HNO_3 . The densities and viscosities of a few ternary $\text{N}_2\text{O}_5/\text{HNO}_3/\text{NH}_4\text{NO}_3$ mixtures at 298 K are listed in Table 9.

Table 9: Density and viscosity of ternary $\text{N}_2\text{O}_5/\text{HNO}_3/\text{NH}_4\text{NO}_3$ mixtures.

Mol-% N_2O_5	Mol-% NH_4NO_3	Density, g/cm ³	Dynamic viscosity, cPs
53.68	0.00	1.558	1.060
53.68	20.72	1.580	4.27
53.00	0.00	1.620	1.553
58.00	17.08	1.594	3.88

Data source: [100]

Solutions of N_2O_5 in HNO_3 are stable only at very low temperatures. Above 0 °C one observes rapid discoloration (brown fumes of NO_2) and effervescence (oxygen bubbles), but only in solutions containing more than 20 mass-% free N_2O_5 . These are mixtures of an oxidizer acid with its anhydride. The physical properties of such binary mixtures are summarized in Table 5–8, also with small percentages of N_2O_4 as an inevitable contaminant. Nitric acid dissolves up to 90 mass-% N_2O_5 .

5.1.4 Viscosity of Dinitrogen Pentoxide/Nitric Acid Mixtures

Viscosity measurements of the $\text{N}_2\text{O}_5/\text{HNO}_3$ system by Taylor, Lyne, and Follows [100] showed a minimum viscosity at 50 mol-% N_2O_5 . Viscosities and surface tensions of solutions of N_2O_4 or N_2O_5 in nitric acid were determined at 278–293 K (5–20 °C), 0–10 mass-% N_2O_4 , or 0–20 mass-% N_2O_5 [102]. The data were fitted to empirical equations as functions of composition and temperature.

5.1.5 Electrical Conductivity of Dinitrogen Pentoxide/Nitric Acid Mixtures

Conductance measurements in the $\text{H}_2\text{O}/\text{N}_2\text{O}_5/\text{HNO}_3$ system over a range of temperatures revealed the presence of a minimum specific conductance at about 96 mass-% HNO_3 and the existence of a negative temperature coefficient of specific conductance for solutions rich in nitric acid [100], see *Encyclopedia of Oxidizers*, chapter “White Fuming Nitric Acid.” The addition of dinitrogen pentoxide to nitric acid increased the conductivity; the addition of water to nitric acid decreased it. According to Taylor, Lyne, and Follows [100], the specific conductance of solutions of N_2O_5 in HNO_3 at room temperature initially increased with increasing concentration of N_2O_5 , attained a maximum near 5 mol-% N_2O_5 , and then decreased with further increase in the N_2O_5 content. This is in contrast to later measurements by Lee and Millen [101], which measured only lower concentrations up to 12 mass-% N_2O_5 and showed a steady increase of electrical conductivity (Figure 3).

Conductance measurements in $\text{H}_2\text{O}/\text{N}_2\text{O}_5/\text{HNO}_3/\text{NH}_4\text{NO}_3$ mixtures at various temperatures and over a wide range of concentrations showed that for all solutions, except those rich in N_2O_5 , the variation of the specific conductance with the con-

Figure 3: Specific conductance of dinitrogen pentoxide/nitric acid mixtures (chart created by Schmidt 2021, based on data from [101])

centration of ammonium nitrate was similar to that observed for many electrolytes in a variety of solvents [103]. With N_2O_5 -rich solvents the specific conductance of ammonium nitrate was observed to decrease with increasing salt concentration. It is difficult to explain why the conductance of a solution containing 61.4 mol-% N_2O_5 falls almost continuously as ammonium nitrate is added. This was regarded as being indicative of an interaction between the salt and one or more of the components of the $\text{HNO}_3/\text{N}_2\text{O}_5$ system. The variation of conductance with temperature was normal in all cases.

5.1.6 Thermodynamic Properties of Dinitrogen Pentoxide/Nitric Acid Mixtures

Heats of mixing and ^1H , ^{14}N , and ^{17}O NMR spectra of $\text{N}_2\text{O}_5\text{-HNO}_3$ mixtures were determined experimentally [104]. The heats of solution increased as the N_2O_5 concentration increased; a sharp peak was observed at an $\text{N}_2\text{O}_5:\text{HNO}_3$ mol ratio of 1:32, and a less pronounced peak was observed at 1:12. These peaks indicated the formation of intermolecular adducts.

The equilibrium properties of the $\text{H}_2\text{O}/\text{HNO}_3/\text{N}_2\text{O}_5$ system were represented using an electrolyte activity model to obtain a representation of both vapor-liquid equilibrium data and the liquid phase composition [105]. Real species concentrations were deduced from Raman spectroscopy measurements. The accuracy of the electrolyte activity model representation compared well with the experimental deviations.

5.1.7 Corrosive Activity of Dinitrogen Pentoxide/Nitric Acid Mixtures

Corrosive attack on wrought iron, cast iron, and stainless steel in white fuming nitric acid is accelerated by the addition of N_2O_5 .

5.2 Dinitrogen Pentoxide/Dinitrogen Tetroxide Mixtures

Mixtures of dinitrogen pentoxide and dinitrogen tetroxide have already been discussed in the chapter "Dinitrogen Tetroxide." Such mixtures would have the advantage that even if a small percentage of N_2O_5 decomposes, because N_2O_4 is both the solvent and the decomposition product, the resulting mixture will still be a mixture of N_2O_4 and N_2O_5 , albeit with a somewhat lowered N_2O_5 content. If N_2O_5 was dissolved in other solvents (e.g., tetranitromethane), the changes in chemical composition would be less tolerable.

The use of a rapid method to measure the N_2O_5 content of $\text{N}_2\text{O}_4/\text{N}_2\text{O}_5$ mixtures allows for adjustments in the N_2O_5 content to the desired nominal level just prior to use. Of course, the storage container may not be hermetically closed, but it needs to have a pressure relief valve to allow the escape of oxygen gas that forms during storage.

5.3 Other Dinitrogen Pentoxide Mixtures

Mixtures of dinitrogen pentoxide with organic nitro compounds, such as nitromethane or tetranitromethane (TNM), have been considered, but very little is known about their stability. One must assume that such mixtures are potentially detonable.

A mixture of 80% dinitrogen pentoxide and 20% TNM freezes at 267 K (-7°C) and is supposedly stable enough to be used as a hypergolic oxidizer with many different fuels [106].

Dinitrogen Tetroxide

Nitrogen commonly forms several different oxides with oxygen, depending on the state of oxidation of the central atom, nitrogen. The state of oxidation of nitrogen can be +1, +2, +3, +4, +5, or +6. The correct names of the six oxides are nitrous oxide, N_2O , nitric oxide, NO , dinitrogen trioxide, N_2O_3 , nitrogen dioxide, NO_2 , dinitrogen tetroxide N_2O_4 , dinitrogen pentoxide N_2O_5 , and nitrogen trioxide NO_3 . Nitrogen dioxide, NO_2 , is used mostly in its dimeric form, dinitrogen tetroxide, N_2O_4 , which can be stored as a liquid at room temperature. The state of oxidation of nitrogen in dinitrogen tetroxide is the same as that in nitrogen dioxide.

The topic of nitrogen oxides had to be distributed over seven chapters because it would have been a very large single chapter that would have made it more difficult for readers to find information on a specific compound. In addition, it would have been difficult to arrange thirty chapters among five subvolumes so that each subvolume would be about the same size. That arrangement was made easier by dealing with smaller-increment chapters. The other six chapters in this series are titled “Nitrogen Oxides,” “Nitrous Oxide,” “Nitric Oxide,” “Dinitrogen Trioxide,” “Nitrogen Dioxide,” and “Dinitrogen Pentoxide.”

Nitrogen forms at least six covalently bound oxides, N_2O , NO , N_2O_3 , NO_2 , N_2O_5 , and NO_3 , which are all thermodynamically unstable with regard to their tendency to decompose to dinitrogen and dioxygen. Dinitrogen tetroxide is the result of dimerization of nitrogen dioxide by way of $\pi^*-\pi^*$ -interactions. As far as rocket propellants are concerned, the first two oxides in this family of nitrogen oxides, nitric oxide and nitrous oxide, have not found the same widespread application as dinitrogen tetroxide and its mixtures with dinitrogen trioxide or nitric acid.

Dinitrogen tetroxide, dinitrogen tetraoxide, N_2O_4 , CAS RN [10544-72-6] (also CAS RN [64476-91-1] or [15969-55-8]) is the dimer of nitrogen dioxide and exists only in equilibrium with its decomposition products. Pure dinitrogen tetroxide free of nitrogen dioxide exists only in the frozen state. Between its freezing point and boiling point, dinitrogen tetroxide is a colorless liquid, but it is often contaminated by traces of dinitrogen trioxide, which may stain it blue. The liquid darkens as the temperature is raised. At temperatures near its boiling point, the vapor space is filled with nitrogen dioxide, which stains it red. At the normal boiling point, the vapor contains 16.1% of NO_2 monomer and is reddish-brown. As the temperature is increased, the proportion of NO_2 monomer increases, and at 423 K (150 °C) the vapor is dark black. Dinitrogen tetroxide has often erroneously also been called “nitrogen tetroxide,” abbreviated NTO, or “nitrogen peroxide.” (Because the NTO abbreviation is common, however, it will be used here.) In the older French literature, the name for N_2O_4 is sometimes *peroxyde d'azote*, which may lead to confusion with real peroxides containing O–O bonds.

Dinitrogen tetroxide has the advantage over liquid oxygen as a rocket propellant oxidizer in that it can be stored as a liquid at room temperature, and it has an advantage over nitric acid in that it is less corrosive and does not decompose during storage. On the other hand, it does not have the same specific-impulse rocket performance as liquid oxygen. In many cases, a compromise between the advantages and disadvantages of dinitrogen tetroxide and nitric acid resulted in a mixture called red fuming nitric acid (RFNA), which has found widespread use as an oxidizer in ballistic missiles and other military applications that require instant readiness and storability.

1 General Information on Dinitrogen Tetroxide

1.1 History of Dinitrogen Tetroxide Use as a Rocket Propellant

Dinitrogen tetroxide had already been considered as a rocket propellant oxidizer during the 1930s in Germany, but it found more widespread use only after World War II [1]. Development work with dinitrogen tetroxide was carried out in the 1950s at the Jet Propulsion Laboratory (JPL) in the United States (at that time administered by the California Institute of Technology in Pasadena) and in the Laboratoire de Recherches Balistiques et Aerodynamiques in Vernon, France.

Next to liquid oxygen, dinitrogen tetroxide is one of the most important rocket propellant oxidizers, and it is certainly the most important storable oxidizer. As such it has been used in many prepackaged rocket propulsion systems that have to be stored in the field under sometimes very challenging environmental conditions until they are put to use. Dinitrogen tetroxide began to replace nitric acid(s) in the late 1950s and early 1960s because it gave higher performance and presented less of a corrosion problem.

Dinitrogen tetroxide is rarely used in the pure form. Most often it is used with small amounts of dinitrogen trioxide added in the form of nitric oxide as a stabilizer and additive to alleviate stress-corrosion cracking (refer to Section 4.1 on mixed oxides of nitrogen).

1.1.1 Summary Publications on Dinitrogen Tetroxide

A good source of physical properties and materials compatibility information is the *USAF Propellant Handbook*, Volume 2: “Nitric Acid/Nitrogen Tetroxide Oxidizers” [2].

2 Production of Dinitrogen Tetroxide

The production of dinitrogen tetroxide is essentially the same as what is described in the chapter on nitrogen dioxide. The conversion of nitrogen dioxide gas to dinitrogen tetroxide liquid occurs as it condenses. Dinitrogen tetroxide is produced in the form of nitrogen dioxide and dimerizes during condensation from the vapor phase. Nitrogen dioxide is produced by catalytic combustion of ammonia in air over a platinum gauze

and in most cases is immediately processed into nitric acid and ammonium nitrate as fertilizer. Because there are no other commercial uses for dinitrogen tetroxide, the U.S. government on several occasions had to negotiate with large-scale nitric acid producers to entice them to divert a small part of the production stream and sell it in the form of high-purity N_2O_4 for use as a rocket propellant. For large-scale nitric acid producers, the N_2O_4 business was not a very profitable operation, and the U.S. government was the main customer. Vicksburg Chemical of Vicksburg, Mississippi, manufactured NTO from 1960 to 2002. Vicksburg filed for bankruptcy and discontinued operations in 2002. After being awarded a \$24 million five-year requirements contract in August 2002, and producing a successful first article sample in January 2003, Mississippi Chemical Corporation (MissChem) filed for Chapter 11 bankruptcy protection in May 2003. DESC Missile Fuels CBU immediately developed and executed a plan to place orders for all known requirements for the duration of the five-year contract and arranged for storage and distribution support to shield customers from the impact should MissChem not be able to meet the full five-year term of its contract. Approximately 1 million pounds of N_2O_4 (\$1.2 million) was ordered from MissChem. MissChem was sold to Terra Industries in 2004. CF Industries Holdings acquired Terra Industries in 2010.

Prior to the invention of the Haber-Bosch process for making ammonia and fixing nitrogen from the air, a large share of nitric acid and nitrogen oxides was made by electrical discharges in air. Because this process required large amounts of electricity, this process (the Birkeland process) was practiced mostly in Scandinavian countries where there was an abundance of cheap hydroelectric power.

Prior to 1958, the Nitrogen Division of Allied Chemical was the sole commercial producer of liquid dinitrogen tetroxide. Other producers entered the market when the demand by the U.S. Air Force (USAF) rose substantially when the design of TITAN intercontinental ballistic missiles (ICBMs) was changed from liquid oxygen/kerosene to NTO/Aerozine-50 to become the next generation, TITAN-II, and the missiles were placed in bomb-proof silos.

Pure NTO is rarely used as rocket propellant. Most NTO is used in mixtures with dinitrogen trioxide. Food Machinery and Chemical Corporation investigated the direct production of mixed oxides of nitrogen (MON)-30 from a commercial nitrogen fixation reactor by chilling the hot reaction products by passing them through a MON-30

bath at temperatures below 222 K (-60°F) and thus quenching the further oxidation of NO to NO_2 [3]. Unfortunately, the commercial process gases contained several percent CO_2 , which also dissolved in the MON liquid and lowered its freezing point. In a separate experiment, CO_2 was bubbled into a MON liquid containing 27% nitric oxide until saturated. By weighing the sample before and after bubbling, it was found that CO_2 was soluble to the extent of about 5% at 222 K (-60°F). This amount of carbon dioxide lowered the freezing point of the mixture by 2 K (3.5°F), from 204.5 to 202.6 K (-91.5 to -95°F). An alternative (but more expensive) method of producing MON starting with NTO would vaporize the N_2O_4 to NO_2 and heat it to 922 K (1200°F), where NO_2 partially dissociates into NO and O_2 , and then quench and condense the mixture at a fast rate that would prevent the reoxidation of NO.

Instead of relying on commercial supplies of NTO of dubious purity that would require elaborate purification at the point of end use, it is possible to manufacture high-purity NTO at the launch site by catalytic oxidation of ammonia with air, followed by cleanup by passing the products through a filter with molecular sieves [4]. This process may be suitable for skid-mounted on-site production of N_2O_4 in locations where local transportation regulations prohibit shipping of N_2O_4 in tank cars through populated areas.

2.1 Purification of Dinitrogen Tetroxide

Because commercial grades of dinitrogen tetroxide are very corrosive and may have been stored in tank cars or other shipping containers for quite some time before it is used, it may contain varying amounts of contaminants, mostly due to absorption of water and leached metals, which would interfere with the intended application as a rocket propellant. In almost all cases, as-received NTO is purified at the point of use before it is loaded into a rocket or a satellite.

Distillation and filtration have been shown by radioisotope tracer techniques to be effective methods of removing iron from brown N_2O_4 [5]. Radioactive ^{59}Fe was added to samples of N_2O_4 , which were then distilled or filtered. Following these operations, the distilled N_2O_4 was checked in a multi-channel analyzer for the presence of radioactivity. Within the measurement limits of the instrumentation, distillation appeared nearly 100% effective in removing iron. Filtration through sintered glass filters and through screen-type stainless steel filters was only of limited effectiveness and pointed to adsorption as the primary filtering mechanism. Passing the N_2O_4 through a column packed with molecular sieve material was shown to be the most effective iron-removal method [6]. Two different molecular sieve materials, Linde LMS-4A and Linde LMS-5A, were evaluated for this purpose, giving similar results (Figure 1). The materials were vacuum-dried at 473 K (200°C) and 0.2 mm Hg prior to use. At the same time, it was shown that passing the NTO through a molecular sieve did not result in any soluble contaminants being leached from the molecular sieve material. In addition to 4A and

Figure 1: Efficiency of iron removal as a function of N_2O_4 /molecular sieve mass ratio. (Reproduced and modified from [6].)

5A type molecular sieves, a type LZ-Y82 was also evaluated as the adsorbent and was a very effective iron adsorber.

Commercial-grade nitrogen tetroxide, before it can be used as rocket propellant, must be upgraded to prevent flow decay problems and to increase the shelf life of the product, thereby providing for longer-duration trouble-free rocket engine performance. In one version of this purification process, the green raw MON material is initially converted (if necessary) to the “red” type by adding an excess of oxygen [7, 8]. Iron salts are less soluble in NTO than in MON and precipitate once all N_2O_3 is oxidized and cooled. Dissolved iron salts and other dirt particulates are then removed by cooling and repeated filtering while cold. The propellant is filtered at each subsequent transfer operation. The stress-corrosion-cracking inhibiting quality of the filtered propellant is then restored by bubbling nitric oxide through the filtered propellant until the desired NO content is achieved. Researchers at the JPL also evaluated molecular sieves as a means of purifying MON [9].

An electrostatic filtration distillation apparatus can be used to significantly reduce contaminants in N_2O_4 vapor and liquid [10]. It operates at ambient temperatures, thus avoiding the need to chill the propellant as in the other, older iron contaminant removal methods. The apparatus described in a patent used an electret vapor filter with a stack of layers of electret material through which the N_2O_4 vapor had to pass. The electret material can be polypropylene or Teflon. The electret vapor filter removed iron contaminants as well as NOCl and volatile iron contaminants. A flow-retarding filter downstream of the electret liquid filter regulated sufficient dwell time for removal of contaminants. The filter was constructed of chemically inert materials to prevent

additional contamination. In a series of tests with different filter materials, initial Fe contents of 0.4–2.6 ppm were effectively reduced to 0.01–0.03 ppm.

The U.S. National Aeronautics and Space Administration (NASA) White Sands Test Facility (WSTF) initially had installed an NTO purification facility based on the chill-and-filter technique, but the method proved to be too time-consuming and ineffective [11]. The problem was that the flow-decay adduct precipitated on the coils of the heat exchanger and was not collected on the membrane filter. The membrane filter with a halfway-tolerable pressure drop still had a pore size of 5 μm , which allowed excessive numbers of smaller particles to pass. Subsequently, NASA started evaluating molecular sieves in 1982 and designed, constructed, and tested a full-scale system for purification of MON [12–14]. Initially, the researchers evaluated 13X, 4A, and 5A, but eventually they selected Linde LZ-Y82 as the best-performing molecular sieve. Both 13X and 5A showed signs of exothermicity during most of the flow periods. The iron concentration in the starting product was 3.6 ppm. With LZ-Y82, a load of 195 g of molecular sieve packed to a bed depth of 27 cm (10.6 in.) was able to treat 108 L (30 gallons) of NTO with average flow rates of 0.15 L/min (0.04 gallon/min) before the column was exhausted and the breakthrough point was reached. The capacity for iron removal was 59×10^{-4} g Fe/g molecular sieve. A filter sized at 0.2 μm was placed downstream of the molecular-sieve column to retain dust that might have been shed from the molecular-sieve pellets. An additional benefit was that this column material not only removed most of the iron but also absorbed water (nitric acid). A large batch (1500 gallons) of NTO had become accidentally contaminated with water, but the propellant was able to be salvaged and brought back into specification limits by passing it through a column packed with 68 kg (150 lb) of LZ-Y82 that had been previously activated by drying at 477–533 K (400–500 °F).

If NTO is to be purified by passing it through molecular-sieve columns, the molecular sieve has to be activated before use to drive off all trapped moisture [15, 16]. Spent molecular sieve can also be reactivated by heating in vacuum. The design of molecular-sieve purification columns can be facilitated by a computer program that takes the initial iron concentration, the desired flow rate, and the desired level of purification as input variables [17].

It is known that distillation will remove iron but not all of the water (nitric acid). Molecular-sieve treatment by passing liquid NTO through a bed of molecular sieves will remove most of the iron but not all. Thus, if one distilled NTO vapors through a packed column with molecular sieves, one would expect to obtain NTO of superior purity, but this process is more time-consuming than either the distillation or the liquid NTO percolation treatment by itself.

Molecular sieve type 3A testing was performed at NASA's WSTF to evaluate the effectiveness of 3A molecular-sieve material to remove water and iron from MON-3 [18]. The overall testing consisted of three test phases. The first phase involved recycled tests performed using an existing molecular sieve unit. This series consisted of eight tests at various pressures, temperatures, and flow rates to determine the rate of wa-

ter removal with contact time and the effect of different operating parameters on the system. The second test phase consisted of two high-iron tests to evaluate the ability of the molecular-sieve material to remove iron from MON-3. The final test phase was a single-pass high-water test that was designed to (1) evaluate the amount of water removed in a single pass and (2) evaluate the effect of water saturation on the ability of the molecular sieve to absorb water. The tests showed that the type 3A molecular-sieve material will remove from 50 to 96% of the water in MON-3, depending on the initial water concentration and on the quantity of water the molecular sieve had previously adsorbed. The tests also demonstrated that the type 3A molecular-sieve material is more effective at removing iron than LZ-Y82, a molecular-sieve material already in use at WSTF for iron removal. Based on the test results, the type 3A material was recommended to replace the LZ-Y82 material in existing molecular-sieve units.

2.1.1 Small-scale Purification of Dinitrogen Tetroxide in the Laboratory

After several small-scale N_2O_4 purification methods were tested in preparation for compatibility testing, a purification system employing BaO treatment and distillation through activated type 3A molecular sieve was close to optimum performance [19].

When N_2O_4 was purified by distillation in glass apparatus in the laboratory, the use of BaO in the distilling flask appeared to aid in the removal of HNO_3 .

Instead of passing the vapor through an absorbent bed of molecular sieve 3A, the absorbent can be combined in direct contact with liquid N_2O_4 in a flask and stirred. This essentially removes all protonated species, mostly HNO_3 . In one experiment, when 1300 mL of red N_2O_4 was combined with 330 g of molecular sieve in a stainless steel cylinder under oxygen pressure and stored for 20 d, the HNO_3 concentration determined by NMR was near the detection limit of the apparatus. At a ratio of 200 g molecular sieve per liter of N_2O_4 , complete deprotonation of 1–2-L batches usually required 2–3 weeks. When this process was scaled up to 34 L (9 gallons), HNO_3 concentration decreased from 5146 to 67 ppm in 45 d. There were no metals leached from the molecular sieve.

In a critical review at the JPL, it was concluded that although distillation was clearly the most effective method, the absorbent-bed approach was considered to be far more practicable. The development of large-scale MON purifiers was subsequently reported at both the JPL and NASA WSTF. In Europe, however, distillation had been preferred, and propellant users expressed concerns about the possibility that absorption beds might introduce silicon and aluminum into the propellant from the molecular sieve. Concern was also expressed about particulate contamination. After detailed consideration, it was decided that the purification efficiency of distillation, together with unreserved acceptance of the technique, established this method as the basis for the Royal Ordnance and Edotek production facilities in the United Kingdom [20].

3 Physical Properties of Dinitrogen Tetroxide

The physical properties of pure dinitrogen tetroxide are summarized here only as a baseline for comparison. Dinitrogen tetroxide is rarely used in the pure form because it contains either unwanted contaminants or additives that were deliberately added to improve its storage and corrosion properties.

The molecular mass of NO_2 is 46.0055 g/mol, and the molecular mass of its dimer N_2O_4 is 92.0110 (1983 IUPAC ^{12}C values).

Due to the dissociation of N_2O_4 into NO_2 , the liquid (under pressure) is a mixture in which the expansion coefficient, specific heat, and thermal conductivity all pass through maxima at temperatures ranging from 313 to 338 K (40 to 65 °C).

3.1 Freezing Point and Phase Behavior of Dinitrogen Tetroxide

Table 1 is a summary of freezing points of pure dinitrogen tetroxide reported in the literature by various investigators. The values differ depending on the purity of the sample and the temperature calibration. Looking at some of the freezing-point and boiling-point data gathered for comparison by Giauque and Kemp [21], it is surprising to see that the earliest data on the freezing point and boiling point of dinitrogen tetroxide date back to 1816 and 1841.

Table 1: Literature summary of freezing points of pure dinitrogen tetroxide.

Temperature		Author	Year	References
K	°C			
262.6	−10.5	Egerton	1914	[22]
261.90	−11.25	Giauque and Kemp	1938	[21]
261.92	−11.23	Whittaker et al.	1952	[23]
261.86	−11.29	Beattie, Bell, and Vosper	1960	[24]

Dinitrogen tetroxide is widely used as the oxidizer in hypergolic bipropellant systems. One of the disadvantages of dinitrogen tetroxide is its high freezing point. In a rocket engine operating in vacuum, propellant evaporating in the injector hold-up volume may cool by evaporation and freeze. Injector clogging by frozen propellants has been a concern for bipropellant engines operating on NTO and Aerozine-50 [25–28]. The freezing point of NTO is only slightly lowered by adding NO, so injector clogging by freezing may be less of a concern with MON-3 or even MON-10.

3.1.1 Phase Behavior at Very High Pressures

Dinitrogen tetroxide and other nitrogen oxides have been subjected to very high pressures in the hope of coercing it into forming a new oxide of nitrogen that might make a better rocket propellant oxidizer. Significantly, Raman spectra of N_2O_4 compressed in a diamond anvil cell showed two new peaks at 1104 and 2208 cm^{-1} , indicating the formation of a new phase when the pressure is increased from 8.8 to 12.3 GPa [29]. It is possible that this new γ -phase is an isomerization from

which has a lower symmetry and may be an intermediate in the transition to the ionic isomer $[\text{NO}^+][\text{NO}_3^-]$ called nitrosonium nitrate. At even higher pressures and temperature, dinitrogen tetroxide and many other nitrogen oxides (most notably nitrous oxide) convert to its ionic isomer nitrosonium nitrate [29]:

The mechanisms governing the transformation between the two forms were studied extensively, but the answers were not unequivocal. Nitrosonium nitrate can be isolated at atmospheric pressure from freshly oxidized NO or dissociated N_2O_4 trapped in a matrix of solid neon. It can be characterized by its IR, Raman, and XRD spectra. Characteristic peaks in the Raman spectra appear at $740\text{ cm}^{-1}(\nu_4)$, $827\text{ cm}^{-1}(\nu_2)$, $1096\text{ cm}^{-1}(\nu_1)$, and $2253\text{ cm}^{-1}(\nu_{\text{NO}^+})$, but they disappear when the pressure is lowered. X-ray diffraction (XRD) at 21 GPa indicates an orthorhombic structure with $a = 5.66\text{ \AA}$, $b = 6.47\text{ \AA}$, and $c = 5.39\text{ \AA}$. Nitrosonium nitrate $[\text{NO}^+][\text{NO}_3^-]$ is denser than mixtures of $\text{N}_2 + \text{O}_2$ or $\text{N}_2\text{O} + \text{O}_2$ under the same pressure. Below 1 GPa , $[\text{NO}^+][\text{NO}_3^-]$ transforms back to molecular N_2O_4 .

At very high pressures (higher than normally encountered in rocket engines), N_2O_4 undergoes transformations into other phases involving nitrosonium nitrate NO^+NO_3^- and dinitrogen pentoxide NO_2NO_3^- ionic crystals [30]. High-pressure/high-temperature Raman and XRD studies of synthesized samples disclosed a transformation of NO^+NO_3^- compound to NO_2NO_3^- crystal at temperatures above ambient and pressures below 9 GPa . High-pressure experiments revealed previously unreported bands in Raman spectra of NO^+NO_3^- and NO_2NO_3^- ionic crystals.

There is evidence for three crystalline modifications, two of which have not previously been observed [31]. The α -phase appeared to be identical with the known low-temperature form, cubic $Im\bar{3}$. Laser irradiation of $\alpha\text{-N}_2\text{O}_4$ caused the formation of a second phase, $\beta\text{-N}_2\text{O}_4$, which was also composed of planar nitro- N_2O_4 molecules and was non-cubic. While the crystal structure of $\beta\text{-N}_2\text{O}_4$ was as yet unknown, polarized Raman spectra gave evidence for the alignment of the N—N bond axis

as opposed to the cubic α -form, which showed no molecular alignment. Both α -N₂O₄ and β -N₂O₄ are molecular crystals. At pressures in the range 15–30 kbar, however, β -N₂O₄ exhibited a reversible phase transition with a large hysteresis to a third structure ionic NO⁺NO₃[−]. In contrast, α -N₂O₄ is stable to at least 76 kbar.

3.2 Boiling Point and Vapor-Phase Composition of Dinitrogen Tetroxide

The boiling point of dinitrogen tetroxide is difficult to determine directly because N₂O₄ at that point has already begun to dissociate into nitrogen dioxide. One does not deal with a pure compound but rather with an equilibrium mixture of two compounds. The boiling points summarized in Table 2 were derived from vapor pressure measurements extrapolated to atmospheric pressure.

Table 2: Literature summary of boiling points of pure dinitrogen tetroxide.

3.3 Density of Dinitrogen Tetroxide

3.3.1 Density of Liquid Dinitrogen Tetroxide

Density data for liquid dinitrogen tetroxide are tabulated in Table 3 and illustrated in Figure 2.

The density of liquid N₂O₄ between 273 K (0°C) and 294 K (21 °C) follows the equation

$$\rho = 1.490 - 0.00215 \times t$$

where ρ is the density in g/cm³ and t is the temperature in °C.

The density of a sample of “reddish-brown” dinitrogen tetroxide with a water content of less than 0.01% (equivalent, it could have been HNO₃) was measured over the temperature range 279.3–351.3 K (6.2–78.2 °C; 43.1–172.8 °F) and curve-fitted by a least-squares method. The polynomial equation fitting these data was [35]

$$\rho = 1.4903 - 2.0517 \times 10^{-3}t - 6.0813 \times 10^{-6}t^2$$

Table 3: Density of liquid dinitrogen tetroxide.

Temperature		Density
°C	K	g/cm ³
0	273.2	1.4906
3.2	276.4	1.4838
6.0	279.2	1.4780
10.3	283.5	1.4688
15.2	288.4	1.4571
19.9	293.1	1.4461
20	293.2	1.4468
25	298.21	1.4342
30	303.2	1.4246
40	313.2	1.3990
50	323.2	1.3746
60	333.2	1.3495
70	343.2	1.3245
80	353.2	1.2990
90	363.2	1.2725

110	383.2	1.2120
120	393.2	1.1688
130	403.2	1.1128
140	413.2	1.0395
150	423.2	0.9410
157	430.2	0.8120

Data source: [34]

**Figure 2:** Density of liquid dinitrogen tetroxide. (Based on [34] data)

where ρ is the density in g/cm^3 and t is the temperature in $^\circ\text{C}$, with a standard error of estimate of $\pm 0.0014 \text{ g/cm}^3$. A similar equation was derived for N_2O_4 that contained small amounts (up to 1.07%) NO; see Section 4.1.4 for MON density data. See also [36].

3.3.2 Density of Solid Dinitrogen Tetroxide

Dinitrogen tetroxide may inadvertently freeze unless some dinitrogen trioxide is added as an anti-freeze. Unlike water, dinitrogen tetroxide does not expand on freezing, so there should be no immediate rupturing danger for the hardware; it will just become non-functional. Literature data of the density of frozen dinitrogen tetroxide are summarized in Table 4. The coefficient of thermal expansion of solid N_2O_4 between 78 and 194 K (-195 and -79 $^\circ\text{C}$) is $3.6 \times 10^{-4} \text{ }^\circ\text{C}^{-1}$.

3.4 Critical Point Properties and Equation of State of Dinitrogen Tetroxide

Based on experimental data published by other authors, pressure-volume-temperature (PVT) relationships of dissociating N_2O_4 were computed and graphed [40]. An equation of state (EOS) of the Wohl type (similar to van der Waals EOS) for dissociating N_2O_4 was derived, which contained an additional term that accounts for attraction and repulsion between molecules. Figure 3 gives the specific PVT diagram of dinitrogen tetroxide vapor. The critical constants used for creating this chart were $T_c = 431.7 \text{ K} = 777 \text{ }^\circ\text{R}$; $p_c = 10.13 \text{ MPa} = 1469 \text{ psia}$; and $V_c = 1.8166 \text{ cm}^3/\text{g} = 0.02910 \text{ ft}^3/\text{lb}$.

Figure 4 gives the specific volume of saturated dinitrogen tetroxide over a wide range of temperatures, from below freezing to near the critical point.

Critical point properties as referenced in other sources are as follows:

$$\begin{aligned}t_{\text{crit.}} & 431.35 \text{ K} = 158.2 \text{ }^\circ\text{C} \\P_{\text{crit.}} & 99 \text{ atm} \\\rho_{\text{crit.}} & 0.56 \text{ g/cm}^3\end{aligned}$$

Figure 3: Specific pressure-volume-temperature diagram of dinitrogen tetroxide vapor. (Republished and modified from [40], with permission of © 1965 American Institute of Aeronautics and Astronautics; permission conveyed through Copyright Clearance Center Inc.)

The EOSs for pure N_2O_4 and pure NO_2 are not available because neither fluid exists in a pure state over the global P - T range. Because of this, ideal assumptions are usually made that allow the composition calculation to be performed. This procedure works reasonably well at low and even moderate densities but is grossly in error in the liquid region. The National Bureau of Standards derived a mathematical model of the EOS

Figure 4: Specific volume of saturated dinitrogen tetroxide. (Republished and modified from [40], with permission of © 1965 American Institute of Aeronautics and Astronautics; permission conveyed through Copyright Clearance Center Inc.)

of dinitrogen tetroxide from literature data and isobaric tables of P – ρ – T and composition for temperatures from the triple point (261.95 K) to 600 K with pressures up to 40 MPa. In doing so, the National Bureau of Standards, in a study of the thermodynamic properties of equilibrium N₂O₄, used the following critical data:

$$\begin{aligned} T_{\text{crit.}} & 431.373 \text{ K} \\ P_{\text{crit.}} & 10.1578 \text{ MPa} \\ \rho_{\text{crit.}} & 550.463 \text{ kg/m}^3 \end{aligned}$$

The pseudo-critical parameters of the hypothetical pure N_2O_4 and the parameters of the hypothetical pure N_2O_4 and NO_2 were taken as adjustable parameters. The least-squares fit gave the following pseudo-critical parameters:

$$\begin{aligned}\text{N}_2\text{O}_4: \quad T_c &= 547.4567 \text{ K} \\ P_c &= 22.0951 \text{ MPa}\end{aligned}$$

$$\begin{aligned}\text{NO}_2: \quad T_c &= 239.3036 \text{ K} \\ P_c &= 10.325 \text{ MPa}\end{aligned}$$

The mathematical model of the equation of state was a 32-term modified Benedict-Webb-Rubin equation for the equilibrium mixture [41]. See also [42–47].

3.5 Velocity of Sound and Compressibility of Dinitrogen Tetroxide

3.5.1 Velocity of Sound and Compressibility of Liquid Dinitrogen Tetroxide

The velocity of sound (also called sonic velocity) of any rocket propellant oxidizer or fuel is an important criterion in trying to understand combustion instabilities that arise from pressure oscillations propagating upstream from the combustion chamber through the injector and into the feed systems. Some launch vehicles have exhibited “pogo” problems due to the compressibility of tall columns of liquids and hidden gas pockets in the system. Some engines started chugging because of insufficient hardness in the feed and injector system, somewhat related to the compressibility of the liquid. The velocity of sound in liquid N_2O_4 is illustrated in Figure 5.

Figure 5: Velocity of sound in liquid dinitrogen tetroxide. (Based on data from [48].)

The data in Figure 5 were curve-fitted from the equation

$$c = 2296 - 4.425T$$

where c is the velocity of sound in m/s and T is the temperature in kelvin.

Not only thermal conductivity but also sound absorption in liquid dinitrogen tetroxide show unusual behavior due to dissociation of N_2O_4 . Sound absorption in liquid N_2O_4 due to relaxation of the dissociation equilibrium exhibits two sound-absorption maxima resulting from relaxation of the dissociation equilibrium [49]. See also [50].

3.5.1.1 Adiabatic Compressibility of Liquid Dinitrogen Tetroxide

The adiabatic compressibility of liquid N_2O_4 was derived from the velocity of sound measurements. The dependence of adiabatic compressibility on temperature is illustrated in Figure 6.

Figure 6: Adiabatic compressibility of N_2O_4 . (Reproduced and modified from [48].)

The data in Figure 6 can be represented by the equation

$$\beta = 5.776 \times 10^{-5} + 5.454 \times 10^{-7}t + 5.185 \times 10^{-9}t^2 - 1.659 \times 10^{-11}t^3 + 5.291 \times 10^{-13}t^4$$

where β is the compressibility in atm^{-1} and t is the temperature in $^{\circ}\text{C}$.

3.5.1.2 Velocity of Sound in Dissociating Gaseous Dinitrogen Tetroxide

The velocity of sound in dissociating gaseous $\text{N}_2\text{O}_4 \rightleftharpoons 2\text{NO}_2$ was determined at various temperatures and used to calculate equilibrium constants as a function of tempera-

ture and pressure [51, 52]. The velocity of sound in dinitrogen tetroxide vapor was measured between 274 and 303 K (1 and 30 °C), at pressures between 17 and 101 kPa (130 and 760 mm Hg), with sound waves between 9 and 93 kHz [53]. The change of the velocity of sound with frequency allows an estimate of the rate of dissociation of dinitrogen tetroxide into nitrogen dioxide, driven by sound energy and the oscillation of local pressure. It has been attempted to measure the rate of dissociation of N_2O_4 vapor by measuring the attenuation of sound waves as a function of frequency. At sufficiently high frequencies, the velocity of sound is independent of frequency because the N_2O_4 dissociation equilibrium cannot adjust itself fast enough to the local pressure fluctuations as the sound wave moves through [54]. At low frequencies, the intensity and travel velocity of the sound wave is diminished because part of the energy goes toward dissociating N_2O_4 . This dissociating equilibrium gas is a good example for demonstrating the capabilities of photoacoustic resonance spectroscopy [55].

A randomly abbreviated sample list of raw velocity of sound data is presented in Table 5, but the wide spread of the data is still disturbing [56]. It also lists the percentages of NO_2 and K_p derived from the pressure measurements. The trend of the velocity

Table 5: Velocity of sound in gaseous dinitrogen tetroxide equilibrium mixture.

157.4	434.6	97.2	9.82

Data source: Allied ChemicalNT-1

Figure 7: Vapor pressure of dinitrogen tetroxide equilibrium mixture. (Reproduced and modified from Allied Chemical.)

The vapor pressures of solid and liquid dinitrogen tetroxide were measured with a mercury manometer by means of an arrangement in which a purge gas of carbon dioxide protected the mercury surface from reaction with the dinitrogen tetroxide. For the range from 261 to 295 K (−12 to 22°C), the following equation gives more accurate data [22]:

$$\log_{10} p_v = 1753.00/T + 8.00436 - 11.8078 \times 10^{-4} T + 2.0954 \times 10^{-6} T^2$$

where $\log_{10} p_v$ is the decadic logarithm of the pressure in cm Hg (NOT mm Hg!!) and T is the absolute temperature in kelvin.

Another vapor pressure equation for the temperature range from 262 to 431 K (−11 to 158°C) was based on a combination of data from three earlier sources

$$\log_{10} p_v = 6.94291 - 2331.98/T + 84567/T^2$$

where p_v is the vapor pressure in atm and T is the temperature in kelvin. Data from this equation were used to construct the graph in Figure 8.

In a similar data analysis of existing data, the raw vapor pressure data from Giauque and Kemp [22] and Schlinger and Sage [36] were combined and fitted to a polynomial equation [41]:

$$\ln p = N_1 + N_2 \chi + N_3 \chi^2 + N_4 \chi^3 + N_5 \chi^4 + N_6 \chi(1 - \chi)^{1.5}$$

where

$$\chi = (1 - T_{tr}/T)/(1 - T_{crit.}/T)$$

Figure 8: Vapor pressure of liquid dinitrogen tetroxide. (Based on data from [48].)

Table 7: Coefficients for vapor pressure equation.

N_1	-3.98267618
N_2	5.680987615
N_3	$4.725629483 \times 10^{-1}$
N_4	$1.036003737 \times 10^{-1}$
N_5	$4.376388591 \times 10^{-2}$
N_6	$3.6714221706 \times 10^{-1}$

Data source: [41]

and $T_{tr} = 261.95\text{ K}$ (triple-point temperature), $T_{crit.} = 431.372\text{ K}$ (critical-point temperature), T is the temperature in kelvin, and the vapor pressure p is in MPa. The coefficients are given in Table 7.

The vapor phase of MON-3 consists of four constituents: N_2O_4 , N_2O_3 , NO_2 , and NO . The vapor pressure is the sum of the partial pressures of these four constituent gases. A new empirical fit to existing vapor pressure data for NTO and MON-3 was compared to other existing fits while showing the accuracy of each as compared to available data [57].

3.6.2 Vapor Pressure of Solid Dinitrogen Tetroxide

Dinitrogen tetroxide as a solid sublimates quite readily, so we must take the vapor pressure of the solid into account. It may be possible to purify dinitrogen tetroxide by sublimation at low temperatures. The vapor pressure of frozen N_2O_4 between 238 K (-35°C) and 173 K (-100°C) listed in Table 8 was measured by a dynamic transference sublimation method and compared to the vapor pressure of an undercooled liquid [21].

Table 8: Vapor pressure of solid dinitrogen tetroxide.

Temperature		Vapor pressure (interpolated)	
$^\circ\text{C}$	K	mm Hg	kPa
-100	173	0.0023	0.0003
-90	183	0.0093	0.0012
-80	193	0.0360	0.0048

Data source: [21]

The vapor pressure of solid dinitrogen tetroxide was measured with a mercury manometer by means of an arrangement in which a purge gas of carbon dioxide protected the mercury surface from reaction with the dinitrogen tetroxide. For the range from 240.3 to 261.9 K (-32.85 to -11.25°C), the following equation gives fairly accurate data [22]:

$$\log_{10} p_v = -2460.000/T + 9.58149 + 7.6170 \times 10^{-3} T - 1.51335 \times 10^{-5} T^2$$

where $\log_{10} p_v$ is the decadic logarithm of the pressure in cm Hg (NOT mm Hg!!) and T is the absolute temperature in kelvin.

Another set of vapor pressure data covering both the solid and liquid ranges of N_2O_4 is shown in Figure 9, taken from [58].

Yet another set of data was used to derive the vapor pressure equation for solid dinitrogen tetroxide:

$$\log p_v = 5.05334 + 763.176/T - 399161/T^2$$

where p_v is the vapor pressure in mm Hg and T is the temperature in kelvin. This equation was used to generate the vapor pressure graph shown in Figure 10.

Figure 9: Vapor pressure of solid and liquid N_2O_4 . (Reproduced and modified from [58].)

3.7 Viscosity of Dinitrogen Tetroxide

One must differentiate between dynamic (also called absolute) viscosity and kinematic viscosity. The SI physical unit of *dynamic viscosity* μ is the Pascal-second ($\text{Pa} \cdot \text{s}$), which is equivalent to $(\text{N} \cdot \text{s})/\text{m}^2$, or $\text{kg m}^{-1} \cdot \text{s}^{-1}$. The cgs physical unit for dynamic viscosity is the *poise*, abbreviated as Ps.

$$1 \text{ Ps} = 0.1 \text{ Pa} \cdot \text{s}$$

$$1 \text{ cPs} = 1 \text{ mPa} \cdot \text{s} = 0.001 \text{ Pa} \cdot \text{s}.$$

The SI unit of *kinematic viscosity* ν is m^2/s . The cgs physical unit for *kinematic viscosity* is the *stokes*, abbreviated as St. It is sometimes expressed in terms of centistokes (cSt).

$$1 \text{ St} = 1 \frac{\text{cm}^2}{\text{s}} = 10^{-4} \frac{\text{m}^2}{\text{s}}$$

$$1 \text{ cSt} = 1 \frac{\text{mm}^2}{\text{s}} = 10^{-6} \frac{\text{m}^2}{\text{s}}.$$

3.7.1 Viscosity of Liquid Dinitrogen Tetroxide

Table 9 is a summary of single-point dynamic viscosity data for dinitrogen tetroxide reported in the literature.

Table 9: Literature summary of dynamic viscosity data of pure dinitrogen tetroxide.

Dynamic viscosity		At temperature		Author	Year	References
cPs	mPa·s	K	°C			
0.35	0.35	311	38	Richter, Reamer, and Sage	1953	[59]
0.422	0.422	293	20	Suarez-Alfonso, Chambers, and Hatz	1961a	[60]
0.396	0.396	298	25	Wright, <i>USAF Propellant Handbook</i>	1977	[2]
0.394	0.394	298	25	Constantine et al.	1968	[48]

As of 1953, there were only limited viscosity data of liquid N_2O_4 at saturated vapor pressure available in the literature. Most of that came only from foreign sources, and some dated back to 1895. Therefore, the primary interest of renewed and more accurate measurements was focused on the development of an analytical expression to describe the effect of temperature on the viscosity of liquid [59]. These data were needed for the prediction of the characteristics of flow or thermal transfer in rocket engines. The viscos-

Figure 11: Effect of pressure with temperature as a secondary variable on the dynamic viscosity of liquid N_2O_4 . (Reprinted and modified from [59], with permission from © 1953 American Chemical Society.)

ity of liquid dinitrogen tetroxide was measured at pressures up to 34.4 MPa (5000 psia) in the temperature interval between 278 and 411 K (40 and 280 °F). A rolling-ball viscometer was employed, which is a stainless steel tube inclined at an angle of approximately 15°, down which a closely fitting stainless steel ball was permitted to roll under the influence of gravity. Figure 11 shows the effect of pressure (with temperature as a secondary variable) on the viscosity of liquid N_2O_4 .

Figure 12 shows the same data with the primary and secondary variable reversed, showing the effect of temperature on the dynamic viscosity of liquid N_2O_4 , with pressure as a secondary variable. The original publication contains tabulated raw measured data and smoothed values of the viscosity as a function of pressure for each of the temperatures investigated.

The same data that served as the source for Figure 12 were reevaluated and curve-fitted to an equation for the dynamic viscosity of liquid dinitrogen tetroxide at the bubble point:

$$\eta = -0.2005 - 72.003/T + 74314.6/T^2$$

where η is the dynamic viscosity in cPs and T is the temperature in kelvin. The data derived from this equation were used to generate the bubble-point line in Figure 13, which also contains viscosity data for higher pressures.

Figure 12: Effect of temperature, with pressure as a secondary variable, on the dynamic viscosity of liquid N_2O_4 . (Reprinted and modified from [59], with permission from © 1953 American Chemical Society.)

Figure 13: Dynamic viscosity of liquid dinitrogen tetroxide at high pressures. (Reproduced and modified from [48].)

Figure 14 shows the dynamic viscosity of liquid dinitrogen tetroxide under its own vapor pressure for higher temperatures, beyond the range of data shown in Figure 11.

Figure 14: Dynamic viscosity of liquid dinitrogen tetroxide under its own saturation vapor pressure. (Chart created by Schmidt 2016, based on data from [2].)

The bubble-point data in Figure 14 can be expressed by the following polynomial equation:

$$\eta = 7.533 - 6.167 \times 10^{-2}T + 2.055 \times 10^{-4}T^2 - 3.234 \times 10^{-7}T^3 + 1.966 \times 10^{-10}T^4$$

where η is the dynamic viscosity in cPs and T is the temperature in kelvin. Table 10 gives the dynamic viscosity of liquid N_2O_4 at 311 K = 37.8 °C at very high pressures.

Gelling of dinitrogen tetroxide will reduce the spill hazard but will substantially increase the viscosity of the oxidizer. The effort to make gelled N_2O_4 often goes hand in hand with efforts to make gelled RFNA. The applications would be very similar. For gelled N_2O_4 properties and gelling agents tested, see Section 8.11.

^aat 311 K = 37.8 °C

Data source: [34]

The values of dynamic viscosity below 284.2 K (11.2 °C) of N_2O_4 were described by a straight line fitting the equation

$$\log \eta = \frac{400}{T} - 1.742$$

where η is the dynamic viscosity in cPs and T is the temperature in kelvin [33]. No discontinuity was apparent.

Viscosity data for MON are in Section 4.1.5.

3.7.2 Viscosity of Gaseous Dinitrogen Tetroxide

Data on the viscosity of equilibrium dissociating dinitrogen tetroxide in the vapor state are insufficient. This difficulty is partially due to the dissociation equilibrium. The viscosity of the equilibrium gaseous system $\text{N}_2\text{O}_4 \rightleftharpoons 2\text{NO}_2$ (for brevity, called NO_2) was measured in the temperature range of 298–443 K (25–170 °C) at pressures from 55 to 505 kPa (0.5–5 atm) employing a rolling-ball viscometer [61]. The viscosity of the equilibrium gaseous system $\text{N}_2\text{O}_4 \rightleftharpoons 2\text{NO}_2$ is shown in Figure 15 in comparison to some literature data. The fact that the viscosity decreases with increases in pressure below 373 K (100 °C) can be explained by the fact that the equilibrium $\text{N}_2\text{O}_4 \rightleftharpoons 2\text{NO}_2$ shifts to the left with an increase in pressure, at the same time increasing the concentration of the less viscous species N_2O_4 .

Figure 15: Dynamic viscosity of dissociating gaseous N_2O_4 . (Reprinted and modified from [61] with permission from © 1964 American Chemical Society.)

By analyzing the experimental viscosity of the dissociating system $\text{N}_2\text{O}_4 \rightleftharpoons 2\text{NO}_2$, the force constants of N_2O_4 and NO_2 have been obtained for the Lennard-Jones (12:6) potential [62]. Calculations made with these force constants have suggested that, in agreement with theory, chemical reaction has no significant effect on the viscosity of a chemically reacting gas mixture.

Dinitrogen tetroxide will rarely be used in the gaseous form as a rocket propellant, but viscosity data for the gas are available as shown in Figure 16. At the higher temperatures, most of the vapor will consist of NO_2 instead of N_2O_4 . Of course, all of the N_2O_4 has to evaporate before it can react with a rocket fuel; therefore, viscosity in the gas phase becomes important. The viscosity of $\text{NO}_2/\text{N}_2\text{O}_4$ vapor in the range of 298–443 K (25–170 °C) can be expressed by the polynomial equation

$$\eta = 123.66 - 7.04 \times 10^{-2}t + 2.0996 \times 10^{-2}t^2 - 1.72 \times 10^{-4}t^3 + 4.290 \times 10^{-7}t^4$$

where η is the dynamic viscosity in μPs and t is the temperature in °C.

Figure 16: Viscosity of dinitrogen tetroxide/nitrogen dioxide vapor at 101 kPa. (Chart created by Schmidt 2016, based on data from [48].)

The pressure dependence at a constant temperature of the dynamic viscosity of a reacting mixture ($\text{N}_2\text{O}_4 \rightleftharpoons 2\text{NO}_2$) was calculated at 300–1000 K and 1–300 bar by using a pseudo-critical constant method and from semi-empirical mixing rules for the Lennard-Jones potential force [63, 64]. The two methods gave almost identical results, which differed by approximately 5–8% from experimental values.

The viscosity of dinitrogen tetroxide vapor expanding to supersonic velocities in a Laval nozzle will depend on the rate at which the $\text{N}_2\text{O}_4 \rightleftharpoons \text{NO}_2$ equilibrium can adjust to the rapidly changing pressure and temperature environment as it expands. Calculations were made for shifting and frozen equilibrium during expansion [65].

3.8 Surface Tension of Dinitrogen Tetroxide

Table 11 is a summary of single-surface tension data for dinitrogen tetroxide as reported in the literature.

Table 11: Literature summary of surface tension data of pure dinitrogen tetroxide.

Surface tension			At temperature		Author	Year	References
N/m	dyn/cm	lb _f /ft	K	°C			
0.02648	26.48	0.001815	298	25	Suarez-Alfonso, Chambers, and Hatz	1961	[66]

1 lb_f/ft = 14.5939 N/m

The surface tension of dinitrogen tetroxide as a function of temperature is illustrated in Figure 17.

The surface tension data in Figure 17 can be expressed by the equation

$$\sigma = 109.00 - 0.3709T + 3.0 \times 10^{-4}T^2$$

where σ is the surface tension in dyn/cm and T is the temperature in kelvin. Surface tension data for MON are in Section 4.1.6.

Figure 17: Surface tension of dinitrogen tetroxide. (Chart created by Schmidt 2016, based on data from [2])

3.9 Thermal Conductivity of Dinitrogen Tetroxide

Table 12 is a short summary of thermal conductivity data for dinitrogen tetroxide as found in the literature.

Table 12: Thermal conductivity of NO₂ and N₂O₄ equilibrium mixture

Physical state	Temperature		Thermal conductivity	
	°C	K	cal cm ⁻¹ s ⁻¹ °C ⁻¹	W m ⁻¹ K ⁻¹
Gaseous	55	328	9.6 × 10 ⁻⁵	0.0402
Liquid	4.4	277.6	3.35 × 10 ⁻⁴	0.140
Saturated liquid	37.8	310.9	2.98 × 10 ⁻⁴	0.125
Saturated liquid	71	344	2.31 × 10 ⁻⁴	0.097

Data sources: Various literature citations
1 mW m⁻¹ · K⁻¹ = 10⁻³ W m⁻¹ · K⁻¹ = 10⁻⁵ W cm⁻¹ · K⁻¹ = 0.000002388 cal s⁻¹ cm⁻¹ °C⁻¹ = 2.388 × 10⁻⁶ cal s⁻¹ cm⁻¹ °C⁻¹; 1 cal s⁻¹ cm⁻¹ °C⁻¹ = 418.68 W m⁻¹ K⁻¹

3.9.1 Thermal Conductivity of Liquid Dinitrogen Tetroxide

The thermal conductivity of liquid dinitrogen tetroxide was determined in an apparatus that consisted of two concentric spherical shells whose temperatures were measured while a known outward-bound radial thermal flux passed between them [68]. The results are illustrated in Figure 18 and tabulated in Table 13.

Figure 18: Thermal conductivity of liquid N_2O_4 . (Reprinted and modified from [68], with permission from © 1956 American Chemical Society.)

Table 13: Experimental values of thermal conductivity of liquid dinitrogen tetroxide.

Temperature		Pressure		Thermal conductivity

344.3	160	31.08	4517.5	0.108	0.0626

Data source: [68]

It is assumed that thermal conductivity graphs presented in the *USAF Propellant Handbook* on N_2O_4 [2] are actually based on measurements of Richter and Sage 1957 [68], just represented in a different format (Figure 19 for several elevated pressures and Figure 20 for the bubble-point pressure).

Figure 19: Thermal conductivity of liquid N₂O₄ at elevated pressures. (Based on data from [48].)

The thermal conductivity of liquid dinitrogen tetroxide from Figure 19 for the ranges of 277–344 K (4–71 °C) and 0.45–31 MPa (65–4500 psia) can be represented by the following equation:

$$\kappa = 3.363 \times 10^{-4} - 7.955 \times 10^{-7}t + 8.231 \times 10^{-9}p - 3.04 \times 10^{-11}pt - 9.36 \times 10^{-9}t^2$$

where κ is the thermal conductivity in cal cm⁻¹ s⁻¹ K⁻¹, p is the pressure in psia, and t is the temperature in °C. To convert from cal cm⁻¹ s⁻¹ K⁻¹ to W m⁻¹ K⁻¹, the conversion factor is 1 cal cm⁻¹ s⁻¹ K⁻¹ = 418.4 W m⁻¹ K⁻¹.

The thermal conductivity of liquid dinitrogen tetroxide from Figure 20 can be represented by the following equation:

$$\kappa = -3.294 \times 10^{-4} + 5.566 \times 10^{-6}T - 1.144 \times 10^{-8}T^2$$

where κ is the thermal conductivity in cal cm⁻¹ s⁻¹ K⁻¹ and T is the temperature in kelvin. See also [69].

Figure 20: Thermal conductivity of liquid N_2O_4 at the bubble point. (Chart created by Schmidt 2016, based on data from [2, 48].)

3.9.2 Thermal Conductivity of and Heat Transfer to Dissociating Gaseous Dinitrogen Tetroxide

For a non-dissociating system with the same physical properties as non-dissociating gaseous N_2O_4 , theoretical calculations would only predict one-ninth of the rate of heat transfer and thermal conductivity as for a dissociating system. Because of the high rate of heat transfer and good thermal conductivity, dinitrogen tetroxide has been considered as a working fluid in chemical heat pipes and as a working fluid in nuclear reactors [70, 71]. Table 14 gives a comparison of predicted thermal conductivity of N_2O_4 with and without equilibrium dissociation. See also [72].

Table 14: Calculated thermal conductivity of the gaseous system $\text{NO}_2/\text{N}_2\text{O}_4$ at 1 atm.

Temperature K	Thermal conductivity, $\text{W m}^{-1} \text{K}^{-1}$		Thermal conductivity, $\text{cal cm}^{-1} \text{s}^{-1} \text{K}^{-1}$	
	With shifting equilibrium	With frozen equilibrium	With shifting equilibrium	With frozen equilibrium
290	0.084	0.013	20.083×10^{-5}	3.110×10^{-5}
300	0.107	0.014	25.668×10^{-5}	3.337×10^{-5}
320	0.147	0.016	35.233×10^{-5}	3.860×10^{-5}
340	0.142	0.018	33.977×10^{-5}	4.427×10^{-5}

Data source: [73]

The thermal conductivity of gaseous dinitrogen tetroxide is higher than one would expect from theoretical considerations. This discrepancy is the result of the fact that in addition to heat transfer by conduction, convection, and radiation (purely physical transport of energy), a portion of the heat is transported as chemical energy. This is a chemical heat pipe where the energy is transported as heat of dissociation. Dinitrogen tetroxide dissociates at the hot end of the heat pipe into NO_2 . NO_2 diffuses to the cold end and recombines there to N_2O_4 , releasing heat. This theory has been confirmed in the course of several experimental investigations.

Heat transfer rates of both heating and cooling for dissociating N_2O_4 gas were experimentally measured under turbulent pipe-flow conditions [74]. The range of the average Reynolds numbers for which these measurements were made was from 6700 to 22000. Thermal flux at the inside surfaces of the tubes ranged from 946 to 26480 W/m^2 (300–8400 $\text{BTU h}^{-1} \text{ft}^{-2}$) for heating and cooling. Wall temperatures of the heater section were varied from 294 to 333 K (70 to 140 °F). Mixed-mean bulk gas temperatures for both heating and cooling were in the range of 295–361 K (72–190 °F). Radial velocity and temperature profiles were measured at various longitudinal positions in the heater section. For this equilibrium gas mixture, heat-transfer coefficients as high as 12 times those for the gas under frozen equilibrium conditions were obtained.

An all-glass apparatus has been used to measure the thermal conductivity of the system $\text{N}_2\text{O}_4 \rightleftharpoons 2\text{NO}_2$ by a thick-wire variant of the hot-wire method in a temperature range of 305–363 K (32–90 °C) and up to a pressure of about 67 kPa (500 mm Hg), measuring the equilibrium constant and the thermal conductivity of the system simultaneously [75]. The discrepancy between the experimental and the calculated values of the heat conductivity, which is particularly large at the lower pressures, showed the necessity of applying non-equilibrium heat-transfer theory to interpret the data. A correlation between dissociation constants and thermal conductivity is presented in Section 5.2 for N_2O_4 .

The kinetics of dissociation, recombination, and relaxation of chemical energy play an important role in the thermal conductivity of the dissociating system $\text{N}_2\text{O}_4 \rightleftharpoons 2\text{NO}_2$, where a chemical accommodation coefficient must be considered [76].

The thermal conductivity of doubly dissociating N_2O_4 involving both the reactions $\text{N}_2\text{O}_4 \rightleftharpoons 2\text{NO}_2$ and $2\text{NO}_2 \rightleftharpoons 2\text{NO} + \text{O}_2$ has been measured between 373 K (100 °C) and 473 K (200 °C) at pressures below 101 kPa (1 atm) using both the absolute hot-wire method and an all-glass apparatus with a glass diaphragm manometer [77]. The results were, however, not in good agreement with the values calculated on the assumption of local chemical equilibrium for both the reactions.

It has been found by conducting measurements at varying pressures that the theoretical estimate of relaxation effects in the heat conductivity of a chemically reacting gas mixture holds only up to a certain upper limit of pressure, beyond which the observed effect becomes insignificant compared with the theoretical predictions [78].

The thermal conductivity of dissociating dinitrogen tetroxide was measured by the hot-wire method with a platinum wire in the temperature range of 290–870 K and

at four pressures (27, 53, 80, and 100 kPa) [79]. The predicted thermal conductivity as a function of temperature at 100 kPa showed two maxima, the first one at 350 K ($143 \text{ mW m}^{-1} \text{ K}^{-1}$) due to $\text{N}_2\text{O}_4 \rightleftharpoons 2\text{NO}_2$ and a second one ($\sim 200 \text{ mW m}^{-1} \text{ K}^{-1}$) at 700 K due to $2\text{NO}_2 \rightleftharpoons 2\text{NO} + \text{O}_2$. See also [80].

Thermal transport properties such as heat capacity, thermal conductivity, and coefficient of thermal expansion of equilibrium-type reacting systems are usually large, non-monotonic functions of temperature. Accordingly, in convective heat transfer to such systems, large heat transfer coefficients dominate. In correlating heat transfer data in reacting systems, it is necessary to have information on the pertinent physical properties of the equilibrium system. Properties such as molecular weight, density, diffusion coefficient, viscosity, thermal conductivity, isobaric specific heat capacity, specific enthalpy, and coefficient of thermal expansion were calculated for the systems

and

Reaction (1) is much more likely to be at equilibrium for most processes than reaction (2) is, since kinetic measurements indicated reaction times for reaction (1) of the order of a microsecond at 298 K (25 °C), whereas reaction (2) is relatively slow [62, 81].

The balanced equations for the intensity of turbulent pulsations of temperature and composition of chemically reacting binary mixtures were used to investigate the effect of chemical non-equilibrium on the characteristics of turbulent heat and mass transfer in turbulent flows in or near the boundary layer [82]. It was shown that in a flow of dissociating dinitrogen tetroxide at subcritical pressure gradients, representations with the usual relations for the turbulent transfer coefficients can be used for the description of the turbulent heat and mass flows, including the effect of pulsations of temperature and composition on the averaged rate of chemical transformations in turbulent flows. The results of numerical calculations of the heat transfer and friction resistance in a flow of dinitrogen tetroxide, with due allowance for the variation of the physicochemical properties of the coolant and the mutual effect of dissociation and turbulence, showed that heat transfer to a dissociating fluid is higher than heat transfer to a non-dissociating fluid.

For predicting the heat exchange of dissociating dinitrogen tetroxide in fully developed turbulent flow used as a working fluid in fast breeder nuclear reactors, it was assumed that in the first stage the medium is a homogeneous gas [83]. Results of calculations and experiments in the range between $\text{Re} = 2 \times 10^4$ and $\text{Re} = 8 \times 10^4$ agreed satisfactorily with each other.

3.10 Heat-Transfer Coefficient of Liquid N_2O_4

With regard to the regenerative cooling of rocket engines using liquid N_2O_4 , it is important to know the heat-transfer properties of the coolant fluid. Dinitrogen tetroxide is well suited for regenerative cooling, but it is not used very often in that capacity [84]. The heat-transfer coefficient at the upper limit to nucleate boiling of dinitrogen tetroxide is low in comparison to other rocket propellants that might also be used as coolants in regenerative rocket engines (Table 15). See also [85, 86].

Table 15: Heat-transfer coefficient of dinitrogen tetroxide in comparison to other rocket propellants.

Coolant liquid	Heat-transfer coefficient q_{ul} at 2.07 MPa = 20.4 atm, 9.1 m/s and 310.9 K = 37.8 °C inlet temperature		Heat capacity at 310.9 K = 37.8 °C	
	kW/cm ²	BTU in. ⁻² s ⁻¹	J g ⁻¹ K ⁻¹	cal g ⁻¹ °C ⁻¹

Data source: [84]

Local heat-transfer coefficients were measured for the liquid nitrogen dioxide/dinitrogen tetroxide system in well-developed turbulent flow in an electrically heated tube of inner diameter 4.9 mm (0.194 in) [87]. The average probable error determined from reproducibility tests was less than 2%. A modification of the Deissler analogy presented earlier was found to predict coefficients that agreed well (0–19% deviation) with the observed results. Some of this deviation may be due to uncertainties in the viscosity data.

Local turbulent heat-transfer coefficients were obtained for the dissociating system $\text{N}_2\text{O}_4 \rightleftharpoons 2\text{NO}_2$ flowing through an electrically heated tube with a length-to-diameter ratio of 40 [88]. Experimental test conditions covered heat flux up to 44000 BTU h⁻¹ ft⁻² = 138.7 kW/m² and mass flow rates up to 130000 lb_m h⁻¹ ft⁻² = 176 kg m⁻² s⁻¹. The maximum tube wall temperature reached from 359 to 572 K.

Heat-transfer coefficients were measured in the boiling $\text{N}_2\text{O}_4 \rightleftharpoons 2\text{NO}_2$ system at ≤ 157 MPa (≤ 1550 atm absolute) and heat fluxes of 34.9 to 872 kW/m² (3×10^4 to 7.5×10^5 kcal m⁻² h⁻¹) [89]. At 0.1–1 MPa (1–10 atm), there was a marked increase in the heat-transfer coefficient with an increase in pressure. There was only an insignificant increase in the intermediate range at 1.8–5.1 MPa (18–50 atm). At 1–2 MPa (10–20 atm),

the heat-transfer coefficient exhibited hysteresis, i.e., the values obtained on increasing the pressure were noticeably higher than those obtained on reducing the pressure.

At a high level of superheating, the thermal transfer properties of N_2O_4 lag behind the flow [90]. See also [91, 92].

The heat-exchange coefficients during the flow of a two-phase vapor-liquid stream of dissociating N_2O_4 in vertical pipes heated by a nuclear reactor were analyzed, and functions were derived for calculating the heat flux under different flow conditions [93].

Dinitrogen tetroxide has been evaluated as the working fluid in nuclear power plants driving a turbine. The condensation of NTO after expansion through the turbine occurs in the return loop of the power plant in vertical pipes [94]. The results of a calculation of the heat exchange and hydraulic resistance during film condensation of NTO in a vertical pipe were compared with experimental data on the condensation of water steam.

Pressure-drop and heat-transfer measurements in a dinitrogen tetroxide closed-loop turbulent flow system indicated that after 3000 h of operation at 35–80 bar, 650–840 K, flow velocities between 30 and 50 m/s, and Reynolds numbers between 6×10^3 and 70×10^3 , the friction losses were increased by 14–19% because of roughening of the surface, but the heat-transfer coefficient had not changed significantly [95].

Experimental heat-transfer data obtained with N_2O_4 boiling and dissociating in a vertical tube were correlated in a set of empirical equations that will allow one to predict heat flux and temperature gradient as a function of boiling condition (undercooled or saturated condition boiling), pressure, flow velocity, and fluid-stream quality [96].

In tests with measuring the boiling heat transfer to flowing MON-3, the critical heat-transfer point was reached when the superheat temperature was about 50 K (50°C) under different flow conditions [97]. Pressure oscillations with 8–22 Hz frequency were observed when MON-3 was boiling. This frequency was similar to the frequency observed with combustion instabilities in a test injector that simulated the actual rocket engine combustion chamber.

3.11 Solubility of Pressurant Gases in Dinitrogen Tetroxide

There are several general science publications that provide the basics of gas solubility and list some solubility numbers in NTO as examples [98–100].

3.11.1 Equilibrium State of Gas Solubility in Dinitrogen Tetroxide

Henry's law describes the maximum amount of pressurant gas that can dissolve in a liquid under equilibrium conditions. Henry's law states that at a constant temper-

ature, the concentration of the gas in the liquid phase is proportional to the partial pressure of the dissolving gas in the gas phase:

$$P_g = X_g \cdot k_{\text{Hp},c} = N_{\text{gas}}/N_{\text{solvent}} \cdot k_{\text{Hp},c}$$

where P_g is the partial pressure of the dissolving gas in the gas phase, X_g is the mol fraction of dissolved gas, $k_{\text{Hp},c}$ is Henry's constant in the dimension of atm L/mol, and N_{gas} and N_{solvent} are the number of mols in the saturated solution.

In reality, the variation of the partial pressure of a gas is never completely linear with variation of mol fraction X_g of gas in the liquid phase, especially when it is considered over the whole of the concentration range from $X_g = 0$ to $X_g = 1$. Nevertheless, for low concentration of gas in liquid phase, when $X_g < 0.01$, the variation of mol fractions usually fit a linear relation within experimental error.

Because there are several forms of equations used to express Henry's law, and all k_{H} may be referred to as Henry's law constants, readers of the technical literature must be quite careful to verify which version of the equation is being used because the constant will have different numbers and different units.

Henry's constant varies with temperature, which is why it would be better to call it Henry's coefficient instead of Henry's constant. Depending on the gas and the solvent, solubility can increase or decrease with increasing temperature. In a closed vessel with liquid at the bottom and gas in the ullage, when the temperature increases, **(1)** the density of the liquid propellant decreases, which leads to a smaller ullage volume and compression of the ullage volume gases. In addition, **(2)** the vapor pressure of the propellant increases, and in some cases **(3)** the gas solubility increases. In tanks with a small ullage volume fraction, the effects of **(1)** and **(3)** are accentuated.

The most common pressurant gases for N_2O_4 and MON are helium and nitrogen, and the solubility of these gases in N_2O_4 and MON has been thoroughly investigated. The solubility data for helium or nitrogen in N_2O_4 available prior to 1964 were inaccurate, and more accurate measurements needed to be made. The solubilities of He, N_2 , O_2 , and Ar in liquid N_2O_4 were measured at moderate pressures (0.5–1.9 atm) and temperatures between 262 and 303 K [101–103]. In all cases Henry's law was obeyed; i.e., the solubility was proportional to the partial pressure of gas dissolved by N_2O_4 . The logarithms of the Henry's constant $K = X/P$ were plotted against reciprocal absolute temperature and gave straight lines, as shown in Figure 21. This illustration is unusual because it shows only three segments of a chart with an uninterrupted ordinate scale. To save space, the three areas of interest were extracted from a complete chart, and each segment has its own ordinate scale. If the data for the solubility of four different gases were combined in one chart, its vertical expanse might occupy an entire page, as would three individual, rectangular charts. This type of graph saves space, but we have rarely seen it done this way. These gases are more soluble in N_2O_4 than in H_2O or other solvents. It would be difficult to extrapolate from the data obtained at 0.5–1.9 atm to higher pressures at which rockets operate. Data for higher pressures would be of more practical interest.

Figure 21: Solubilities of He, N₂, O₂, and Ar in liquid N₂O₄. (Reproduced and modified from [104].)

Although dissolving a gas (here identified by the subscript i) in a liquid solvent (identified by the subscript j) is a physical process in which no chemical changes are involved, the process

can be expressed by an equilibrium constant similar to those used for chemical reactions:

$$K = \frac{\text{ppm}_i}{P} = 10^6 M_i \frac{X_i}{M_j} P_i$$

where M_i and M_j are the molecular masses of the gas and the solvent, respectively; X_i is the mol fraction of the gas in the solution; and P_i is the pressure above the solution

(in units of atmospheres). K is temperature dependent, and a plot of $\log K$ versus $1/T$ gives a linear correlation similar to an Arrhenius curve:

$$\log K_i = \frac{A}{T} + B$$

where A and B are dimensionless constants tabulated in Table 16.

Table 16: Gas solubility equation constants for gases dissolving in NTO.

Gas	A	B	Solubility at 1 atm, in units of ppm	
			at 273 K	at 298 K
He	-521	2.3874	3.0	4.3
N ₂	-153	2.8194	182	203
O ₂	-145	3.0367	320	355
Ar	-104	2.9757	394	424

Data source: [103]

The solubilities of O₂, NO, and N₂O₃ in liquid N₂O₄ were measured over a modest pressure range between 0.3 and 1.9 atm at 262, 273, and 298 K (-11, 0, and +25 °C) [105]. The results showed that Henry's law was obeyed for all pressures at each temperature for O₂ and at low pressures for NO and N₂O₃. The standard free energy, enthalpy, and entropy of solution for each gas were computed [106]. Oxygen solubility data indicated that no formation of other nitrogen oxides occurred in the oxygen-saturated N₂O₄ under the conditions of this test.

During the Apollo program for the testing of the lunar module ascent and descent propulsion systems at NASA WSTF, large quantities (up to 4.5 m³ [1200 gallons]) of Aerozine-50 and N₂O₄ were saturated with gaseous helium at pressures ranging from 344 to 1690 kPa (50–245 psia). To promote rapid absorption of the helium by the propellant, equipment was designed to expose a large surface area of the propellant to a helium atmosphere [107]. Before the as-received propellant was loaded into an auxiliary conditioning unit, it was vented at atmospheric pressure in the ready storage units for 3 h to allow any gaseous nitrogen (normally used for the tank or vessel pressure maintained in the ullage during shipping and storage) dissolved in the propellants to come out of solution. The dinitrogen tetroxide bubble-point pressure as a function of calculated 100% helium saturation pressure was then graphed for six different temperatures. For the measurement ranges encountered, the relationship between temperature or pressure and helium content for a given constant pressure or temperature was linear. The dissolved helium can be calculated from the equation

Helium content of N₂O₄ = -0.1771 + (0.001568 × pressure) + (0.001656 × temperature)

where helium content is in cubic centimeters STP per gram N_2O_4 , pressure is in pounds per square inch gauge, and temperature is in °F. Similar data were obtained for Aerozine-50. In a later program, similar helium solubility data were obtained for MON-1 and MMH (see *Encyclopedia of Liquid Fuels*, chapter “Methylhydrazine”).

Pressure conditions for a MON-3 propellant tank in Eurostar satellites with the intention of being launched on the Space Transportation System (Space Shuttle) but (for unforeseen reasons) returning to Earth after a failed launch attempt while in orbit were calculated, taking into consideration the out-of-spec heating of the spacecraft sitting in the payload bay during re-entry and the heat soaking back if the shuttle had to land in hot desert climate conditions at White Sands or Edwards Air Force Base [108]. The maximum soak-back temperature was predicted to be 318 K (45 °C). The increased temperature has several effects on the tank pressure, which were considered in the model:

- Thermal expansion of the propellant
- Partial pressure of pressurant gas released on heating
- Propellant vapor pressure
- Solubility and release of pressurant gas
- Tank volume expansion

The Eurostar oxidizer tank has to stay within the 17.7 bar MEOP. Experiments with 94.4% fill level were made with a 1-L bomb with 35-bar operating pressure and 70-bar proof test pressure, and the experimental results were compared to predictions from the computer model. Because dissolution of He in MON is a slow process, or only the top layer becomes saturated, zero helium solubility was assumed as the worst case in the computer model.

Experience gained with NTO and MMH tank pressurization during launch preparations for Galileo and Mars Observer space probes was compared with literature data (Table 17) on helium solubility in these propellants [109].

Techniques were developed for achieving the required levels of helium saturation in monomethylhydrazine (MMH) and NTO during launch preparations, and the measured values were evaluated for equilibrium solubilities of He in liquid propellants as known to the industry at that time. At that time (1990), there were still enough uncertainties in the published He saturation values to warrant further basic experimental studies. From the several possible methods for measurement, the manometric measurement of gas volume from a frozen sample of propellant was the recommended method for gas analysis.

Dissolved pressurant gases and the degree of gas saturation may affect the performance (ignition delay, injector boiling, dribble volume expulsion) of bipropellant rocket engines [110].

3.11.2 Rate of Pressurant Gas Absorption into Dinitrogen Tetroxide

The rate of solution of a gas in a liquid is highly dependent upon the extent of agitation and mixing. Gas diffusion through an immobile liquid can take months to equilibrate. The configuration of the propellant supply tanks at a launch or test facility will determine the most efficient saturation technique for its system. Gas saturation of liquids can be accelerated by aeration, bubbling, and stirring. In a tank without an expulsion diaphragm, immediately after pressurizing a stagnant unsaturated propellant in a satellite or upper-stage propellant tank with pressurant gas and locking up the system, the pressure in the ullage starts decaying because a fraction of the gas from the ullage goes into solution. The rate at which the pressure decays depends on a large number of variables and has been the subject of several analytical modeling studies. There is little published data against which to test the validity of those models. In a stagnant tank containing NTO or MON in direct contact with the pressurant gas (e.g., in a surface-tension propellant management device [PMD] tank, not a bladder or diaphragm tank), it may take 20–30 d to achieve a fully saturated propellant. Because it is not desirable to keep the pressurized satellite on the launch pad for so long, and the feed pressure will drop as soon as the system is being used anyway, most satellites are launched with only partially saturated propellant and saturation changes during the mission. The amount of propellant saturation affects the performance of cavitating venturi used as flow limiters in some feed systems.

The aerospace industry has developed several methods to minimize the adverse effects of gas solubility variations on propulsion subsystem performance reproducibility. Temperature variability and effect of the rate at which pressurant gas flows into

the ullage, causing a limited amount of turbulence in the liquid, make this a source of uncertainty. In trying to achieve a nominal design pressure at the time of launch, one can either

- pre-saturate the propellant with pressurant gas in the ground support equipment (GSE) propellant cart before loading
- initially pressurize to above the specified launch pressure and wait for the equilibrium to establish itself at the nominal pressure
- pressurize once, wait several days, and then top the propellant tank off just before launch

All three methods have shortcomings. In method **(1)**, some of the pressurant gas is lost during transfer from the GSE into the satellite; in method **(2)**, the tank may not be designed for the higher pressure required to hold all the gas that will eventually dissolve; and method **(3)** requires the propellant loading crew to suit up and enter the hazardous area twice. The rate of gas absorption depends on whether the tanks are first pressurized at a satellite processing facility and then moved, which may agitate the propellant and enhance mixing, or whether the satellite is attached to the payload adaptor and remains still, with the tanks then being pressurized. In the latter case, the pressurant gas would have to diffuse through the liquid from the top layer of the liquid to the bottom of the tank to achieve complete saturation. It has been observed that diffusion varies with the density of the liquid. The higher the density, the slower the diffusion. It seems that for low-density propellants, less time is required to reach the saturation level.

Some satellite designers have added a dip tube and a dispersing element to feed the pressurant to the bottom of the liquid instead of to the top, but that adds weight and introduces an additional failure mode. Others have recirculated the propellant for several hours before launch to achieve equilibrium. Even if an elastomer-bladder positive expulsion device is used to separate pressurant gas and propellant, sufficient pressurant gas may diffuse through the bladder and saturate the propellant.

The rate of solution of N_2 in liquid N_2O_4 was measured in terms of the change of pressure with time at 5.1 and 7.6% ullage at 293 K (20 °C) and at 6.6% ullage at 273 K (0 °C) [104]. In preparation for the test, the N_2O_4 was distilled into a cylindrical container with a capacity of 97 mL, 40-mm diameter, and 95-mm height, which approximated the scaled-down dimensions of a typical propellant tank. After pressurization, pressure readings were taken every 10–15 min for the first hour and every 30 min for the subsequent 3 or 4 h. At the end of a run, the N_2O_4 was stirred vigorously for about 10 min, and then the final pressure reading was taken. The pressure decay was slower with increasing ullage and increasing temperature because of the relative masses of gas and liquid and the diffusional barrier near the interphase both in the gas and the liquid (Figure 22). The pressure decay did not fit a reasonable reaction rate, although it appeared to follow a first-order reversible reaction rate after 40 min.

Figure 22: Pressure decay of nitrogen pressurant in a N_2O_4 tank. (Reproduced and modified from [104].)

The absorption rate of helium into NTO can be expressed by the equation

$$N_i = 3.27 \times 10^{-5} (P - P_s) A$$

where N_i is the mass convection rate of He into the propellant in mol/h, P is the total pressure of the ullage gas, P_s is the pressure when the propellant is totally saturated with helium, and A is the liquid-gas interface area in m^2 [111]. The pressure decay of a freshly pressurized tank can be predicted by the equation

$$(P - P_s)/(P_0 - P_s) = \exp\left(3.27 \times 10^{-5} \frac{ART}{V}\right)\theta$$

where P is the total pressure of the ullage gas, P_0 is the initial pressure, P_s is the pressure when the propellant is totally saturated with helium (all pressures in atm), T is the temperature in kelvin, A is the liquid-gas interface area in m^2 , V is the total volume of the ullage in m^3 , and θ is the time in h.

A very detailed treatise of the effect of the rate of gas absorption on spacecraft operations, as well as an attempt to model the process in sufficient detail so that pressure in the ullage of a propellant tanks can be predicted as a function of the time elapsed since locking up of the system, are provided in [112]. By knowing the speed of the pressure decay, it would be possible to compute the necessary initial elevated filling pressures that would then drop to the desired pressure at launch time. Measured pressure-decay data from the European Space Agency (ESA) Cluster spacecraft and a number of American satellites were used to predict the pressure decay in liquid MON-propellant and MMH-propellant tanks of the ESA Meteosat Second Generation (MSG) and Rosetta spacecraft [113]. That study was based on measured data of pressure histories from several different spacecraft, including some that were referenced in [114]. See also [115–117].

The Japanese H-II Transfer Vehicle (HTV) has four main thrusters (500N) used for orbit control and 28 reaction control system (RCS) thrusters (110N) used for reaction control. The HTV has multiple engine and long propellant supply lines, which makes its operation and surge-pressure spikes dependent on the saturation level of the propellant pressurant gas. A visual bubble-point technique and gas chromatography were used to determine the helium saturation level prior to ground-level testing of the propulsion system [118].

Because of the solubility of helium in propellants (MMH and NTO), tank pressure may decrease for several days after initial tank pressurization on the ground prior to launch. A model is necessary to predict the pressure loss. Conventional models had assumed that the tank was static. However, in the case of the Japanese HTV, propellant sloshing occurred by movement of the HTV between buildings on the ground prior to launch. Tank pressure loss in HTV tanks could not be predicted by the conventional model because of the sloshing. An improved numerical solubility model expresses the influence of sloshing on helium solubility by solving the vertical distribution of helium concentration in the stratified tank contents [119]. Not only does the pressurant gas dissolve in and diffuse through liquid dinitrogen tetroxide, but dinitrogen tetroxide and nitrogen dioxide vapors will also diffuse in the opposite direction through the gas atmosphere in the ullage volume. The diffusivity of nitrogen tetroxide evaporating into a nitrogen or a helium atmosphere has been determined by theoretical calculations and two experimental test methods [120]. The first method used the rate of evaporation in an open cylindrical vessel. The second method studied the evaporation kinetics in a closed vessel. The measured diffusivity of dinitrogen tetroxide in nitrogen was $0.098\text{--}0.101\text{ cm}^3/\text{s}$, and the diffusivity of dinitrogen tetroxide in helium was $0.398\text{--}0.415\text{ cm}^3/\text{s}$.

3.11.3 Rate of Pressurant Gas Release from Dinitrogen Tetroxide

Helium evolution during the transfer of helium-saturated propellant under zero-gravity conditions in space causes two-phase gas/liquid flow from the supply tank, gas injection into the receiving tank, and potential liquid discharge and propellant loss from the vented receiving tank if the PMD fails to keep the liquid puddle in place. An engineering study was made of propellant transfer taking place between two similar surface-tension PMD tanks whose maximum storage capacity was approximately 2.55 m^3 , each transferring a maximum on-orbit propellants of 4082 kg (9000 lb_m) (fuel and oxidizer). The transfer line was approximately 1.27 cm in diameter and 6096 cm in length. This system was supposed to serve the International Space Station propulsion module (ISSPM) if the Russian propulsion module had been further delayed [121, 122]. Work on ISSPM in the United States was discontinued after the Russian propulsion module Zvezda was launched after an extended delay. The propellant transfer rate was assumed to begin at approximately 11 L/min and would subsequently drop to approximately 0.5 L/min. The tank nominal operating pressure was approximately 1827 kPa (absolute). The line pressure drops for NTO at 11 L/min were approximately 302 kPa, assuming single-phase flow, but would have been higher for two-phase flow. These pressure-drop scenarios caused the helium-saturated propellants to release excess helium. For tank ullage venting, the maximum volumes of helium evolved at tank pressure were approximately 57 L (2 ft³) for NTO. In addition to releasing pressurant gas helium, MON may also have lost some NO during transfer.

The rate of bubble formation in pressurized dinitrogen tetroxide upon sudden pressure release determines the quality of flow of the discharging liquid, resulting in non-steady two-phase gas-liquid flow in channels [123]. A study was made of the effect of non-equilibrium phase transformations in NTO on the dynamics of vapor bubbles in the case of sudden occurrence of a pressure drop.

3.11.4 Analysis of Propellant for Dissolved Gases

Samples of propellant for gas analysis should be obtained at the pressure and temperature of the holding tanks. The best technique places the sampling cylinder as part of a pressurized, recirculating loop, but most test systems cannot accommodate such a loop. A simpler and less accurate technique is the filling of an evacuated sampling cylinder. However, such a filled cylinder will have no ullage and must not be allowed to warm up on its way to the laboratory for analysis; otherwise, it would over-pressurize and rupture due to thermal expansion. The dissolved gases can then be analyzed by gas chromatography.

3.12 Thermodynamic Properties of Dinitrogen Tetroxide

Based on experimental data published by other authors, temperature-entropy relations, enthalpy-temperature relations, and PVT relations of dissociating N_2O_4 were computed and graphed [40].

Further study was undertaken because of the lack of experimental data on the enthalpy of dissociating nitrogen tetroxide [124]. A calculation of the entropy (S) and enthalpy (H) of dissociating N_2O_4 was performed in the temperature range 300–1500 K and pressure range 1–140 atm, taking into account the deviation of reacting N_2O_4 from ideal gas behavior. The calculation was carried out on the basis of general thermodynamic functions of the thermodynamic theory of empirical corrections and was based on generalized tables. The calculated S and H values were then used for plotting H – S and T – S diagrams.

Thermodynamic properties of the chemically reactive system $\text{N}_2\text{O}_4 \rightleftharpoons 2\text{NO}_2 \rightleftharpoons 2\text{NO} + \text{O}_2$ have been evaluated over a pressure range of 0.005–200.0 atm and a temperature range of 200–900 K based on computations for the Lennard-Jones potential [125]. In these calculations, the dissociation of dinitrogen tetroxide to nitrogen dioxide, nitric oxide, and oxygen, and the effect of pressure on the equilibrium constants for the system of reactions $\text{N}_2\text{O}_4 \rightleftharpoons 2\text{NO}_2$ and $2\text{NO}_2 \rightleftharpoons 2\text{NO} + \text{O}_2$ had to be taken into account.

The ideal gas chemical thermodynamic properties for NO , NO_2 , N_2O_3 , and N_2O_4 for the temperature range of 50–5000 K were evaluated by a statistical thermodynamic method using an updated set of molecular parameters [126].

Researchers at the National Bureau of Standards conducted a thorough literature survey and compiled all thermodynamic data for the N_2O_4 equilibrium mixture on a uniform basis [41]. A search of the world's literature revealed a substantial experimental data base but few correlations of those data, and the correlations that did exist either covered only portions of the P – ρ – T surface or involved ideal gas assumptions that, for a wide range of pressures and temperatures, resulted in substantial inaccuracies. A computerized search of the literature produced 172 titles concerned with N_2O_4 . On the basis of the titles alone, 98 of the 172 appeared to be of possible use in the study. A mathematical model of the EOS of nitrogen tetroxide was derived from the literature data. Isobaric tables of P – ρ – T and composition for temperatures from the triple point (261.95 K) to 600 K with pressures to 40 MPa were compiled. The thermodynamic data of the equilibrium mixture were affected by the chemical equilibrium for the system. The mathematical model of the equation of state was a 32-term modified Benedict-Webb-Rubin equation. The EOS for N_2O_4 did not perform well for derived thermodynamic properties such as specific heat capacity, and the correlation of N_2O_4 thermodynamic properties was only partially complete. See also [127].

3.12.1 Heat Capacity of Gaseous Dinitrogen Tetroxide

Most heat capacity data are derived from infrared (IR) spectra and molecular structure quantum mechanical calculations; few data are actually obtained by calorimetry. The calculations derived from IR spectra are extended to high temperatures at which the molecule may no longer be able to exist. Such tabulations have only limited practical use, but we list them here for the sake of completeness.

The most detailed thermodynamic data can be downloaded from the NIST Chemistry WebBook site [128]. The heat capacity of undissociated gaseous dinitrogen tetroxide as a function of temperature can be calculated from the following polynomial equation

$$C_p^\circ = A + B \times \tau + C \times \tau^2 + D \times \tau^3 + \frac{E}{\tau^2}$$

where C_p is the molar heat capacity in $\text{J mol}^{-1} \text{K}^{-1}$, τ is the temperature in kelvin divided by 1000, and A, B, C, D, and E are constants listed in Table 18 for two different temperature ranges. One must note that N_2O_4 is unstable at temperatures above 298 K, and the column for the higher temperature range of 1100–6000 K is only of academic value. It is not very practical to list thermodynamic data for a compound that is unstable at the temperature range listed. It would be much more important to have more accurate thermodynamic data for liquid dinitrogen tetroxide.

Table 18: Thermodynamic property polynomial equation coefficients for dinitrogen tetroxide gas.

Temperature range, K	500–1000	1000–6000
A	34.05274	128.6220

Data source: [128]

3.12.2 Heat Capacity of Liquid Dinitrogen Tetroxide

The heat capacity of the equilibrium $\text{N}_2\text{O}_4 \rightleftharpoons 2\text{NO}_2$ mixture consists of two components: **(1)** a frozen contribution, corresponding to an inert, non-reacting mixture of NO_2 and N_2O_4 , and **(2)** a reaction contribution to take into account the heat of dissociation. The reaction contribution to C_p , is approximately 5–10 times the inert contribution.

The isobaric specific heats, refractive indices, and viscosities at 1 atm of dinitrogen tetroxide were determined at bubble-point pressures for a number of temperatures in the range of 305–378 K (90–220 °F) [129].

Figure 43 (in Section 5.2) shows that the change in degree of dissociation α with temperature is greatest (steepest) at temperatures from 327 to 344 K. Therefore, the contribution of the heat of reaction to the equilibrium heat capacity is greatest in this temperature range, and the curves in Figure 23 show a maximum of C_p at each pressure [130].

Figure 23: Heat capacity of dinitrogen tetroxide equilibrium mixture as a function of temperature and pressure. (Reprinted and modified from [130] with permission from © 1962 American Chemical Society.)

The heat capacity of liquid dinitrogen tetroxide as a function of temperature can be calculated from the following polynomial equation

$$C_p^\circ = A + B \times \tau + C \times \tau^2 + D \times \tau^3 + \frac{E}{\tau^2}$$

where C_p is the molar heat capacity in $\text{J mol}^{-1} \text{K}^{-1}$, τ is the temperature in kelvin divided by 1000, and A, B, C, D, and E are constants listed in Table 19.

Table 19: Thermodynamic property polynomial equation coefficients for liquid dinitrogen tetroxide.

Temperature range, K	298–500
A	89.16313
B	178.9141
C	0.929459

Data source: Giauque and Kemp [21]

Heat-capacity data calculated with above equation were tabulated in Table 21.

Most heat-capacity data are for isobaric conditions at constant pressure, but a few isochoric specific heat-capacity data at constant volume were recorded (liquid at 288 K [15 °C] and 101 kPa [1 atm]) $27.9 \text{ J mol}^{-1} \text{K}^{-1} = 6.67 \text{ cal mol}^{-1} \text{°C}^{-1}$. From the ratio of the heat capacity at constant pressure to heat capacity at constant volume, one derives the adiabatic coefficient $\gamma C_p/C_v$, which is 1.303 for the liquid at 288 K = 15 °C and 101 kPa = 1 atm [131].

The heat capacity of dinitrogen tetroxide was measured in the temperature range of 410–484 K at densities between 2.0121 and 9.8039 g/cm³ and for pressures up to

Molecular mass: 92.0110 g/mol

35 MPa using a high-temperature and high-pressure adiabatic calorimeter [132, 133]. The measurements were performed in the one-phase region at 17 isochores (11 liquid and 6 vapor densities), including coexistence curve and critical region. The liquid and vapor one-phase isochoric heat capacities, temperatures, and densities at saturation were extracted from experimental data for each measured isochore. Some of the experimental data (TS , ρS) and C_v along isochores and at saturation are compared with values derived from isobaric heat capacity C_p , sound velocity, and PVT measurements. The critical parameters for N_2O_4 ($T_c = 431.072 \text{ K}$) were measured using a quasi-static thermogram method. See also [134–136].

The heat capacity of dinitrogen tetroxide was measured in the temperature range of 410–484 K at densities between 201.21 and 980.39 kg/m and for pressures up to 35 MPa using a high-temperature and high-pressure adiabatic calorimeter [132]. The measurements were performed in the single-phase region at 17 isochores (11 liquid and 6 vapor densities), including data points along the coexistence curve and into the critical region. The liquid and vapor one-phase isochoric heat capacities, temperatures, and densities at saturation were extracted from experimental data for each measured isochore. Some of the experimental data along isochores and at saturation were compared with values previously derived from isobaric heat capacity C_p , sound velocity, and PVT measurements. The critical parameters for N_2O_4 were measured using a quasi-static thermogram method.

3.12.3 Heat Capacity of Solid Dinitrogen Tetroxide

Smoothed heat-capacity data for solid dinitrogen tetroxide, taken from a curve-fitted formula based on measurements between 16.8 and 291.28 K, are tabulated in Table 22.

Table 22: Smoothed molar heat capacity at constant pressure values for solid N_2O_4 .

3.12.4 Enthalpy of Formation of Dinitrogen Tetroxide

3.12.4.1 Enthalpy of Formation of Gaseous Dinitrogen Tetroxide

The standard enthalpy of formation of N_2O_4 gas is $\Delta H_f^\circ \text{gas} = 9.079 \text{ kJ/mol} = 2.17 \text{ kcal/mol}$ [128]. The enthalpy of formation of gaseous dinitrogen tetroxide as a function of temperature can be calculated from the following polynomial equation

$$H^\circ - H^\circ_{298.15} = A\tau + \frac{B \times \tau^2}{2} + \frac{C \times \tau^3}{3} + \frac{D \times \tau^4}{4} - \frac{E}{\tau} + F - H$$

where H is the enthalpy in kJ/mol, τ is the temperature in kelvin divided by 1000, and A , B , C , D , E , F , and H are constants listed in Table 18 for two different temperature ranges. Other sources report N_2O_4 (gaseous) +9.828 kJ/mol (+2.349 kcal/mol) [22].

3.12.4.2 Enthalpy of Formation of Liquid Dinitrogen Tetroxide

The enthalpy of formation of liquid N_2O_4 is listed in [128] as $\Delta H_f^\circ \text{liquid} = -19.56 \text{ kJ/mol} = -4.675 \text{ kcal/mol}$. The enthalpy of formation of liquid N_2O_4 as a function of temperature can be calculated from the following polynomial equation

$$H^\circ - H^\circ_{298.15} = A\tau + \frac{B \times \tau^2}{2} + \frac{C \times \tau^3}{3} + \frac{D \times \tau^4}{4} - \frac{E}{\tau} + F - H$$

where H is the enthalpy in kJ/mol, τ is the temperature in kelvin divided by 1000, and A, B, C, D, E, F, and H are constants listed in Table 19.

Other sources list the enthalpy of formation of liquid N_2O_4 as

$$\text{N}_2\text{O}_4 \text{ (liquid)} - 19.56 \pm 1.7 \text{ kJ/mol} = -4.676 \pm 0.4 \text{ kcal/mol} \quad (\text{JANNAF})$$

3.12.4.3 Enthalpy of Formation of Solid Dinitrogen Tetroxide

The enthalpy of formation of solid N_2O_4 is listed in [128] as $\Delta H_f^\circ \text{solid} = -35.05 \text{ kJ/mol} = -8.377 \text{ kcal/mol}$.

3.12.5 Heat of Fusion of Dinitrogen Tetroxide

From the difference of the enthalpies of formation for solid and liquid N_2O_4 as listed in [128], one can calculate the heat of fusion at 298 K as $15.49 \text{ kJ/mol} = 3.702 \text{ kcal/mol}$.

Other sources list the heat of fusion (ΔH)_{fusion} (at 261.9 K = -11.2°C) as $14.652 \text{ kJ/mol} = 3.502 \text{ kcal/mol}$ [22].

3.12.6 Heat of Evaporation of Dinitrogen Tetroxide

From the difference of the standard enthalpies of formation for liquid and gaseous N_2O_4 as listed in [128], one can calculate the heat of evaporation at 298 K as $28.64 \text{ kJ/mol} = 6.845 \text{ kcal/mol}$.

Other sources give the heat of vaporization (leading to an equilibrium mixture of $\text{N}_2\text{O}_4 \rightleftharpoons 2\text{NO}_2$) (ΔH)_{evap}, (at 294.3 K = 21.15°C) as $38.11 \text{ kJ/mol} = 9.110 \text{ kcal/mol}$ [22].

3.12.7 Heat of Dissociation of Dinitrogen Tetroxide

The dissociation equilibrium of dinitrogen tetroxide is discussed in Section 5.2 under thermal stability and chemical reactions. From the dissociation equilibrium measurements at different temperatures, one can calculate the heat of dissociation: $\Delta H^\circ_0 = 12873 \text{ cal/mol} = 12.873 \text{ kcal/mol}$ and $\Delta H^\circ_{298} = 13873 \text{ cal/mol} = 13.873 \text{ kcal/mol}$ as confirmed by accurate measurements by [22]. See also [32].

3.12.8 Entropy of Gaseous Dinitrogen Tetroxide

The standard entropy of formation of gaseous dinitrogen tetroxide at 298 K and 101 kPa is 308.54 J mol⁻¹ K⁻¹ [128]. The entropy of gaseous dinitrogen tetroxide as a function of temperature can be calculated from the following polynomial equation

$$S^\circ = A \times \ln(\tau) + B \times \tau + \frac{C \times \tau^2}{2} + \frac{D \times \tau^3}{3} - E/(2 \times \tau^2) + G$$

where S° is the enthalpy in J mol⁻¹ K⁻¹, τ is the temperature in kelvin divided by 1000, and A, B, C, D, E, and G are constants listed in Table 18 for two different temperature ranges.

Other sources [21] list the following entropy data:

$$S_{298}\text{NO}_2 \text{ (gaseous) } 57.47 \text{ cal mol}^{-1} \text{ }^\circ\text{C}^{-1}$$

$$S_{298}\text{N}_2\text{O}_4 \text{ (gaseous) } 72.73 \text{ cal mol}^{-1} \text{ }^\circ\text{C}^{-1}$$

3.12.9 Entropy of Liquid Dinitrogen Tetroxide

The standard entropy of formation of liquid dinitrogen tetroxide at 298 K and 101 kPa is 209.20 J mol⁻¹ K⁻¹ [128]. The entropy of liquid dinitrogen tetroxide as a function of temperature can be calculated from the following polynomial equation

$$S^\circ = A \times \ln(t) + B \times t + \frac{C \times t^2}{2} + \frac{D \times t^3}{3} - E/(2 \times t^2) + G$$

where S° is the enthalpy in J mol⁻¹ K⁻¹, t is the temperature in kelvin divided by 1000, and A, B, C, D, E, and G are constants listed in Table 19.

Other sources [137] give the entropy of liquid N₂O₄ as

$$S_{298}\text{N}_2\text{O}_4 \text{ (liquid) } 50.00 \text{ cal mol}^{-1} \text{ }^\circ\text{C}^{-1}$$

By application of the third law of thermodynamics to the calorimetric measurements, the entropy of the gas, which is dissociated to the extent of 16.1% into nitrogen dioxide at the boiling point, was found to be 80.62 cal mol⁻¹ °C⁻¹ of gas as N₂O₄ [21]. From a consideration of the available data on the equilibria

in combination with spectroscopic data for the several substances and the experimental entropy value given above, a number of quantities of thermodynamic interest have been evaluated for N₂O₄(G), $S_{298.1}^0 = 72.73 \text{ cal }^\circ\text{C}^{-1} \text{ mol}^{-1}$ and for NO₂(G), $S_{298.1}^0 = 57.47 \text{ cal }^\circ\text{C}^{-1} \text{ mol}^{-1}$. These values, which are the ones that should be used in ordinary thermodynamic calculations, do not include the nuclear spin entropy, $R \ln 3 = 2.183$, for each nitrogen atom. The absolute entropies are N₂O₄(G), $S_{298.1}^0 = 77.10$; NO₂(G), $S_{298.1}^0 = 59.65 \text{ cal }^\circ\text{C}^{-1} \text{ mol}^{-1}$ and for the reactions: $2\text{NO}_2 \rightleftharpoons \text{N}_2\text{O}_4$, $\Delta F_{298.1}^0 = -1110 \text{ cal}$, $\Delta H_{298.1}^0 = -13693 \text{ cal}$; $\text{N}_2 + 2\text{O}_2 \rightleftharpoons \text{N}_2\text{O}_4$, $\Delta F_{298.1}^0 = 23440 \text{ cal}$, $\Delta H_{298.1}^0 = 2239 \text{ cal}$; $\text{NO} + \frac{1}{2}\text{O}_2 \rightleftharpoons \text{NO}_2$, $\Delta F_{298.1}^0 = -8375 \text{ cal}$, $\Delta H_{298.1}^0 = -13562 \text{ cal}$; $\frac{1}{2}\text{N}_2 + \text{O}_2 \rightleftharpoons \text{NO}_2$,

$\Delta F^0_{298.1} = 12275 \text{ cal}$, $\Delta H^0_{298.1} = 7964 \text{ cal}$. The experimental entropy value obtained in this investigation, together with band spectrum data, has made possible a much better correlation of the various measurements on the above equilibria than was previously possible. Accepting the band spectrum evidence that NO_2 is a symmetrical non-linear molecule, it was possible to show from the equilibrium measurements that the statistical weight of the normal electronic state is 2. The calculations did not permit an estimate of the potential barrier concerned in the rotational oscillations of these groups.

3.13 Molecular Structure of Dinitrogen Tetroxide

It would be useful to fully understand the molecular structure of dinitrogen tetroxide and all of its isomers and high-pressure phase variants if it would lead us to a more energetic form of this molecule that would push the specific impulse beyond 300 s. Isomers of N_2O_4 have been identified but not yet tested as rocket propellants. Dinitrogen tetroxide can exist in two isomeric forms, the more common symmetrical structure

and an unsymmetrical structure

The unsymmetrical isomer can exist in a *cis* and a *trans* stereoisomeric form.

Experimental results, such as NO_2 hydrolysis and the hypergolicity of hydrazine/dinitrogen tetroxide pair, have been interpreted in terms of NO_2 dimers. Such interpretations are complicated by the possibility of several forms for the dimer: symmetric N_2O_4 , *cis*- $\text{ONO}-\text{NO}_2$, and *trans*- $\text{ONO}-\text{NO}_2$. Quantum mechanical studies of these systems are complicated by the large resonance energy in NO_2 , which changes differently for each dimer and changes dramatically as bonds are formed and broken. As a result, none of the standard methods for quantum mechanical orbital calculations is uniformly reliable. Using density functional theory (B3LYP) and several *ab initio* methods (MP2, CCSD[T], and GVB-RCI), the enthalpy barrier to form *cis*- $\text{ONO}-\text{NO}_2$ was calculated as 7.9 kJ/mol (1.9 kcal/mol), whereas the enthalpy barrier to form *trans*- $\text{ONO}-\text{NO}_2$ was calculated as 55.2 kJ/mol (13.2 kcal/mol) [138]. The enthalpy barrier for N_2O_4 isomerizing to *trans*- $\text{ONO}-\text{NO}_2$ was calculated as 183.7 kJ/mol (43.9 kcal/mol), ruling out the possibility of such an isomerization playing a significant role in the gas-phase hydrolysis of NO_2 . A much more favored path

is to form *cis*-ONO—NO₂ first and then convert to *trans*-ONO—NO₂ with a 10.0 kJ/mol (2.4 kcal/mol) enthalpy barrier.

An unstable isomer of dinitrogen tetroxide, ONO—NO₂ (*asym*-N₂O₄), was photolyzed in an Ar matrix at 11 K at 436 and 510 nm [139]. *Asym*- to *sym*-N₂O₄ (O₂NNO₂) isomerization was the major process at 436 nm, and other products observed were NO, *cis*-(NO)₂, *asym*-N₂O₃ (O₂NNO), and N₂O₅. Irradiation of *asym*-N₂O₄ above 510 nm induced no reaction.

The N₂O₄ isomerization in the gas phase has an energy barrier of 129.7 kJ/mol (31 kcal/mol) at 298 K. This energy barrier may be reduced due to the interaction of the N₂O₄ isomers with water or nitric acid clusters adsorbed on surfaces. Calculations using the *ab initio* and the polarizable continuum model (PCM) methods indicated that the Gibbs free-energy barrier for this reaction in an aqueous medium is reduced to 88.3 kJ/mol (21.1 kcal/mol) [140]. Other calculations using the transition state theory (TST) model estimated that the N₂O₄ isomerization may be as fast as $2.0 \times 10^{-3} \text{ s}^{-1}$ in aqueous phase at room temperature. The activation energy of the N₂O₄ isomerization is about 87.9 kJ/mol (21 kcal/mol). The rate coefficient for this reaction is considerably fast, $1.2 \times 10^{-2} \text{ s}^{-1}$, in aqueous phase at $T = 373 \text{ K}$.

3.13.1 Molecular Structure of Gaseous Dinitrogen Tetroxide

Another possible isomer of N₂O₄ that might form as an intermediate during NO oxidation in the gas phase would be a peroxide structure:

This structure is very unlikely and has not yet been confirmed. Nevertheless, its energy surface has been calculated [141].

Dinitrogen tetroxide vapor that is vented to vacuum at the end of a launch phase may directly cool to frozen NTO. The residual vapor of N₂O₄ at the venting stage may develop an aerodynamic problem that is linked with the vapor-phase nucleation phenomena of the propellant. A study based entirely on computational molecular treatment examined the problem by considering the thermodynamic free energies of N₂O₄ clusters, leading to the evaluation of nucleation flux rates of critical nuclei at incipient nucleation from a molecular perspective [142].

3.13.2 Molecular Structure of Liquid Dinitrogen Tetroxide

A computational study of the microdynamics of translational, orientational, and vibrational motions in liquid N₂O₄ based on molecular dynamics simulations, including all degrees of freedom of vibrating N₂O₄ molecules and atom-atom Lennard-Jones (LJ) potentials with and without Coulomb potentials (LJ + C and LJ, respectively), showed that the velocity and angular momentum correlation functions decayed faster to more evident negative parts and that both the translational and orientational diffusion slowed down [143]. Simulated rotational correlation functions

for LJ + C agreed reasonably with those derived from Raman spectroscopy, while those for LJ were found to decay too fast. Vibrational correlation functions for the N–N stretching ν_3 mode were calculated, and the vibrational spectra were obtained from their Fourier transforms. Results of the simulation were compared with the isotropic Raman band shapes in liquid N_2O_4 measured earlier [144].

3.13.3 Molecular Structure of Solid Dinitrogen Tetroxide

Single-crystal neutron diffraction measurements of frozen dinitrogen tetroxide showed that it crystallized in cubic crystals, space group I_{m3} ; $Z = 6$ [145]. The crystal lattice is a body-centered cubic with six N_2O_4 molecules in the unit cell. The lattice parameter, measured at seven temperatures, increased from 7.6937(6) Å at 20 K to 7.7925(6) Å at 140 K. The observed N–N bond length and $\angle\text{O–N–O}$ angle were invariant between 20 and 100 K at values 1.7562(± 4) Å and 134.46(± 6)°. The observed N–O bond length increased linearly from 1.1855(9) Å at 100 K to 1.1893(5) Å at 20 K. *Ab initio* calculations gave a reasonable value for the N–N bond length: 1.80 Å and a corrected value of 1.74 Å.

The structure of the metastable monoclinic modification of N_2O_4 was redetermined from XRD diffractometer data [146]. The temperature range in which it is possible to study this modification depends on the amount of impurity. At 228 K (–45°C) the structure was refined in space group $P2_1/n$ (no. 14), with lattice constants $a = 591.7(1)$, $b = 475.8(1)$, $c = 644.1(1)$ pm, $\beta = 116.34(2)^\circ$, and $R = 0.032$. The structure contained planar N_2O_4 molecules.

The atomic and molecular interactions in a crystal of $\alpha\text{-N}_2\text{O}_4$ have been studied by quantum topological theory of molecular structure using high-resolution, low-temperature XRD data [147]. The experimental electron density and electrostatic potential were then reconstructed with the Hansen-Coppens multipole model. The application of the quantum theory of atoms in molecules and crystals (QTAIMC) indicated two types of intermolecular bond paths between O atoms in crystalline $\alpha\text{-N}_2\text{O}_4$, one measuring 3.094 Å and the other measuring 3.116 Å. It was found that the intermolecular interactions in $\alpha\text{-N}_2\text{O}_4$ are accompanied by the correlation of energy-density “bridges,” lowering the local potential energy along the intermolecular $\text{O}\cdots\text{O}$ bond paths in the electron density, while the exchange energy density governs the shape of associated molecules.

3.13.4 Bond Lengths and Bond Strengths in Dinitrogen Tetroxide

A reinvestigation of the structure of N_2O_4 in the gas phase at 252 K (–21°C) by electron diffraction has given results in good agreement with earlier studies so far as the molecular shape is concerned, but the size of the molecule appears to be about 0.9% larger than originally thought [148]. The results for the coplanar (D_{2h} symmetry) model were as follows: $r \text{ N–N} = 1.782 \text{ Å}(0.0083)$, $r \text{ N–O} = 1.190 \text{ Å}(0.0018)$, $\angle\text{ONO} = 135.4^\circ(0.58)$, $l \text{ N–N} = 0.0816 \text{ Å}(0.0178)$, $l \text{ N–O} = 0.0381 \text{ Å}(0.0019)$, $l \text{ O}_1\text{O}_2 =$

0.0493 Å(0.0040), $1 \text{ N} \cdots \text{O} = 0.0729 \text{ Å}(0.0061)$, $1 \text{ O}_1\text{O}'_1 = 0.0970 \text{ Å}(0.0167)$, and $1 \text{ O}_1\text{O}'_2 = 0.0730 \text{ Å}(0.0114)$. These distances and root-mean-square amplitudes are r_a and l_a values; the parenthesized values are 2σ and include estimates of systematic error. The $-\text{NO}_2$ groups have a structure very similar to that of NO_2 itself. The very long N—N bond and its large amplitude of vibration imply a weak link and are in accord with the low dissociation energy.

Dinitrogen tetroxide is a weakly bound dimer of NO_2 . The molecule is characterized by two NO_2 groups whose geometrical parameters are virtually identical with those found in free NO_2 gas. The most prominent geometrical feature found in N_2O_4 is the exceptionally long N—N bond as well as its planar structure [149]. This geometry is based on a series of both gas-phase electron diffraction and solid-state neutron diffraction measurements indicating that the N—N bond length lies between 1.756 and 1.782 Å. This is in stark contrast to the N—N bond length found in hydrazine, whose N—N bond length is known to be 1.47 Å, and tetrafluorohydrazine, whose N—N bond is $1.489 \pm 0.007 \text{ Å}$. This unusual geometry has prompted a number of explanations and discussions in the literature. It was suggested that the molecule was held together by a π -only bond, while Pauling pointed out the need for an N—N—O bond that would accommodate the two open-shell electrons centered on the nitrogen atoms from the two NO_2 fragments.

3.13.5 Torsional and Rotational Barriers in Dinitrogen Tetroxide Molecule

The rotation of two halves of the molecule around the long axis of the N_2O_4 molecule is not unhindered but is similar to the situations in N_2O_3 or N_2H_4 , in which the rotation has barriers where the orbitals of the outer atoms overlap and repel each other. Torsional energy potentials for N_2O_4 and N_2O_3 were calculated based on optimized geometries of the respective 90° -twisted saddle points [150]. These potentials were refined by obtaining potential energies of points along the intrinsic reaction coordinate. A comparison was made between these *ab initio* potentials and an analytical form based on a two-term cosine expansion in terms of the N—N dihedral angle. The shapes of these two potential curves were in close agreement. The torsional barriers in N_2O_4 and N_2O_3 obtained from the calculations were 2333 and 1704 cm^{-1} , respectively. For N_2O_4 the torsion fundamental frequency from the intrinsic reaction coordinate potential was 87.06 cm^{-1} , which was in good agreement with the experimentally reported value of 81.73 cm^{-1} . N_2O_4 and N_2O_3 exhibit strong hyperconjugative interactions of in-plane O lone pairs with the central N—Ns* anti-bond. The torsional barriers in these molecules arise principally from a combination of 1,4 interactions and hyperconjugation.

The shape of the potential energy function governing internal rotation about the N—N bond has been determined [151]. Based on the infrared spectrum in the region of $200\text{--}650 \text{ cm}^{-1}$ and analysis of the sequence of weak bands near 540 cm^{-1} involving a combination of the ν_6 (NO_2 rocking) and ν_4 (torsion) modes, it was concluded that

in the ground vibrational state, the height of the barrier at the staggered conformation is $1900 \pm 200 \text{ cm}^{-1}$.

3.14 Dipole Moment of Dinitrogen Tetroxide

The dipole moment of N_2O_4 gas is 0.55 Debye. The dipole moment of NO_2 gas is 0.39 Debye.

3.15 Molecular Orbital Calculations of Dinitrogen Tetroxide

With the advancement of computational chemistry and the continued interest in the unusual molecular structure of dinitrogen tetroxide with its labile N—N bond, there have been numerous molecular orbital theoretical chemistry calculations with the intent to predict the dissociation energy of the N—N bond and the energy levels of the infrared and Raman active vibrations in the molecule.

While other people theorized that the labile N—N bond in N_2O_4 is a π -only bond, Hartree-Fock linear combination of atomic orbitals molecular orbital (LCAO-MO) calculations performed on a basis of symmetry orbitals formed from a minimal Slater basis set predicted that there is only a small amount of N—N π -bonding [152]. A bond energy analysis showed that the lowest state is markedly stabilized by N—N—O three-center interactions.

Localized molecular orbitals were derived from the molecular orbitals calculated by a complete neglect of differential overlap (CNDO) method for N_2O_2 , N_2O_3 , and N_2O_4 , and the theoretical Lewis structures were given with bond angles and bond lengths [153]. The molecules have σ -type nitrogen-nitrogen bonds of high p -orbital character, but no π bonds. Oxygen lone electron pair delocalization to both nitrogen atoms is anti-bonding, reducing the strength of the nitrogen-nitrogen bond.

A redetermination of the barrier to rotation around the N—N bond of N_2O_4 focused attention on the primary valence bond explanation of the “*cis*-O—O overlap” contribution to this barrier [154]. The explanation involved *cis*-O—O overlap-dependent resonance between covalent (NO_2NO_2) structures with “long” or formal N—O bonds, as well as resonance of these structures with the ionic ($\text{NO}_2^-\text{NO}_2^+$, $\text{NO}_2^+\text{NO}_2^-$) structures that can be obtained from them via *cis*-O—O electron transfer in the planar conformer. The results of some *ab initio* valence bond calculations for both N_2O_2 and N_2O_4 were used to illustrate this phenomenon.

A non-empirical valence bond method investigating the conformation of N_2O_4 showed that the π resonance energy of the planar conformer between the two NO_2 fragments was only 3.60 kJ/mol, so the planarity cannot result primarily from the presence of N—N π bonding [155]. A study of the origin of the rotation barrier for N_2O_4 indicated that the variations of the one-electron orbital energies of the $\text{N}_2\text{P}\pi$ and $\text{O}_2\text{P}\pi$ atomic

orbitals as well as their electron populations were responsible for the stability of the planar conformer compared with the skew conformer.

The molecular parameters of N_2O_4 were determined by large-scale *ab initio* calculations using a multi-configurational second-order perturbation method and basis sets of double-zeta to quadruple-zeta quality [156]. With the largest basis set employed, the structural equilibrium parameters were determined to be $r_{\text{N-N}} = 1.7040 \text{ \AA}$, $r_{\text{N-O}} = 1.1906 \text{ \AA}$, and $\angle \text{N-N-O} = 112.55^\circ$. The potential energy barrier at the staggered conformation of the molecule was found to be 2313 cm^{-1} ($23 \text{ kJ/mol} = 6.6 \text{ kcal/mol}$), and the binding energy of the N—N bond was calculated to be 4616 cm^{-1} ($55 \text{ kJ/mol} = 13.2 \text{ kcal/mol}$).

Ab initio studies of dinitrogen tetroxide were performed to predict the equilibrium geometry, harmonic vibrational frequencies, and dissociation energy ($\text{N}_2\text{O}_4 \rightarrow 2\text{NO}_2$) [157]. The structure was optimized at the self-consistent field, configuration interaction, and coupled-cluster levels of theory with large basis sets. At the highest level of theory, the N—N bond distance was $1.752 \text{ \AA}$, in excellent agreement with the experimental value of $1.756 \pm 0.01 \text{ \AA}$. In addition, the harmonic vibrational frequencies were predicted with an average absolute error of 51 cm^{-1} relative to experimental fundamental values, with differences largely attributed to anharmonic effects. The predicted dissociation energy was 30.1 kJ/mol (7.2 kcal/mol), in fair agreement with the experimental value of 53.1 kJ/mol (12.7 kcal/mol).

3.16 Optical Properties of Dinitrogen Tetroxide

3.16.1 Infrared Spectra of Dinitrogen Tetroxide

Infrared spectra of dinitrogen tetroxide (and nitrogen dioxide) are of importance for analytical methods for the quality control of NTO and MON and for leak detection and surveillance in propellant storage areas. When the literature was studied in search of information on IR absorption of nitrogen oxides, most of the publications were found to deal with N_2O_4 or NO_2 as atmospheric pollutants. Most of the work was done with nitrogen oxides with their natural isotope composition, but additional work was done with isotope-labeled nitrogen oxides in order to identify the atoms and mode of vibrations of the molecule responsible for specific absorption bands. Isotope labeling facilitates the assignment of absorption bands to specific rotations and vibrations and their harmonics, for IR as well as for Raman and microwave spectra.

The IR spectrum of dinitrogen tetroxide has been obtained between 5500 and 320 cm^{-1} for the gaseous, liquid, and solid states of this substance [158]. In general, the spectrum of N_2O_4 remained practically unaltered in going from one phase to another. The same four intense absorptions, presumably fundamentals, always appeared within 15 cm^{-1} of 1735 , 1255 , 745 , and 4404 cm^{-1} . It was very difficult to purify the N_2O_4 and obtain samples that were free of N_2O_3 . The wide-range, low-resolution scans shown in Figure 24, 25, and 26 were obtained with a model 21 Perkin-Elmer

Figure 24: Infrared spectrum of gaseous N_2O_4 at approximately 40 and 2 cm Hg pressure at 296 K (23°C) in a 10-cm path length Pyrex cell. spectrometer equipped with a NaCl prism. This is a historic instrument similar to one the author of this book once worked with, which was a model 21 Perkin-Elmer spectrometer that carried the very low serial number 0030.

Table 23 gives a comparison of the four fundamentals in the infrared absorption and Raman fluorescence spectra. The assignments are only preliminary and may have to be revised based on more recent and more accurate data. Comparing the infrared and Raman frequencies for the solid, it is seen that there are no real coincidences except between 1728 and 1724 cm^{-1} . The latter is not surprising because these have both been assigned to characteristic N—O anti-symmetric stretching modes. Thus, the data strongly support the center of symmetry of the structure that was indicated by XRD. The consistency of the IR and Raman spectra in going from the solid to the liquid and gaseous states is remarkable. The spectra support the planar structure of the molecule in all three states. From these and other data, it was speculated that the internal barrier of rotation is about 12.1 kJ/mol (2.9 kcal/mol).

Table 23: Comparison of the four fundamentals in the infrared and Raman spectra of dinitrogen tetroxide.

Spectrum	Infrared			Raman		Assignment
Physical state	Gas	Liquid	Solid	Liquid ^b	Solid ^c

Data source: [158]

Infrared studies have been made of several oxides of nitrogen, including NO₂ and N₂O₄, trapped at liquid-helium temperatures in matrices of Ar, N₂, O₂, CO₂, H₂, or N₂O [161]. NO₂ was found as the monomer, the known stable dimer of planar struc-

ture, and two new dimers. One of these had the $\text{ONO}-\text{NO}_2$ structure, and the other may be the twisted V_d form of the stable dimer.

Isotope labeling helps to identify IR absorption bands and assign them to specific vibrations and rotations. The IR spectra of gaseous and liquid $^{15}\text{N}_2\text{O}_4$ have been observed from 340 to 5500 cm^{-1} , and the Raman spectra of liquid and solid $^{15}\text{N}_2\text{O}_4$ have been recorded as well [162]. The corresponding spectra of $^{14}\text{N}_2\text{O}_4$ were observed as a baseline to provide an accurate measure of the isotope shifts. Assignments of all 11 active fundamental frequencies could be made. These assignments fit the product rule within experimental error and accounted for all observed overtones.

The temperature dependence of the IR spectra of N_2O_4 and N_2O_3 in the solid phase at liquid-nitrogen temperatures has been investigated [163]. From these spectra of both ^{14}N and ^{15}N isotope-labeled molecules, absorption bands that may be assigned to unstable isomers of these nitrogen oxides could be identified. A speculative interpretation of these absorption bands was made by assuming the existence of two unstable forms of N_2O_4 and one unstable form of N_2O_3 . Their existence was later proven by other techniques.

The integrated IR absorption intensities as a function of temperature have been measured for one NO_2 band and for four N_2O_4 combination bands in the spectral region from 1 to $5\text{ }\mu\text{m}$ [164]. The temperature was varied from 323 to 373 K ($50\text{--}100^\circ\text{C}$) for the gas-phase studies and from 298 to 373 K ($25\text{--}100^\circ\text{C}$) for the liquid-phase experiments. Saturated vapors were used in all experiments. The optical depth was varied by using a series of spacers in a specially designed IR absorption cell capable of handling both liquid and gas. Measured intensities for N_2O_4 combination bands in the liquid and gas phases were compared and found to differ by less than 16% for three out of four combination bands studied; for the fourth band, the observed difference was about 50%. Results for all of the combination bands investigated indicated that the integrated intensities varied approximately as a function of $1/T$ in the temperature range under consideration.

Infrared spectra of gaseous $\text{NO}_2/\text{N}_2\text{O}_4$ were obtained under conditions that allowed study of both strongly and weakly absorbing features [165]. These spectral features were then assigned with the aid of vibration-rotation band shape theory. Weakly absorbing sequence bands were identified that contained torsional vibrations. The rocking frequency of the $-\text{NO}_2$ group, the only mode that had not been observed directly, was estimated from a third-law entropy calculation. The frequencies provided for the first time a reliable determination of all the vibrational frequencies of N_2O_4 . The observation of the torsional mode frequencies allowed an internal rotation potential function to be estimated which has a barrier height of $2\text{--}3\text{ kcal/mol}$. It was suggested that in addition to the $\text{N}-\text{N}$ bond, weak σ bonds formed between the *cis* oxygens stabilize the eclipsed oxygen configurations and tend to lock the N_2O_4 molecule into a planar configuration. The planarity of N_2O_3 and the stability of *cis* $(\text{NO})_2$ can also be explained by these weak oxygen σ bonds.

Infrared absorptions of N_2O_4 in the ν_9 band at CO laser frequencies were monitored while an $\text{NO}_2/\text{N}_2\text{O}_4$ sample was subjected to visible radiation from an argon laser to dissociate it [166]. Double resonance signals corresponding to a two-molecule scheme involving the $2\text{NO}_2 \rightleftharpoons \text{N}_2\text{O}_4$ chemical equilibrium were observed and interpreted.

The question of whether the formation of the NO^+NO_3^- (nitrosonium nitrate), the ionic form of nitrogen dioxide, via the decomposition of the $\text{ON}-\text{O}-\text{NO}_2$, is an intermolecular or intramolecular process was addressed via temperature-dependent and concentration-dependent Fourier-transform infrared spectroscopy (FTIR) studies of mixed films of N_2O_4 with CCl_4 [167, 168]. It was concluded that the process of nitrosonium nitrate production, both during deposition of disordered solid films of nitrogen dioxide and during their subsequent warming, is intermolecular but not order dependent, and a mechanism was tentatively suggested.

A complete set of band identifications was derived from a Fourier transform absorption spectrum of N_2O_4 in the gas phase at medium resolution between 650 and 7000 cm^{-1} under various temperature conditions [169].

Based on the IR spectrum in the region $200\text{--}650\text{ cm}^{-1}$ and analysis of the sequence of weak bands near 540 cm^{-1} involving a combination of the ν_6 (NO_2 rocking) and ν_4 (torsion) modes, it was concluded that in the ground vibrational state, the height of the barrier at the staggered conformation is $1900 \pm 200\text{ cm}^{-1}$ [151].

The integrated band intensities of the ν_9 and ν_{11} bands of N_2O_4 around 1757 and 1261 cm^{-1} were measured by varying temperature and pressure and found to be as follows: S-band (ν_9) = 9.60, 9.10, 8.80 and S-band (ν_{11}) = 5.93×10^{-17} , 5.70×10^{-17} , and $5.33 \times 10^{-17}\text{ cm/molecule}$ at 293.15, 277.25, and 261.65 K, respectively [170].

The rotationally resolved jet-cooled IR spectra of the b-type ν_9 (b2u) fundamental band at 1757 cm^{-1} and the a-type ν_{11} (b3u) fundamental band at 1261 cm^{-1} of the N—O stretches of N_2O_4 have been recorded with a diode laser [171]. The ν_9 band was found to be unperturbed, and it was possible to assign nearly 100% of the observed lines with a signal-to-noise ratio greater than 2. In contrast, most of the K_a states of the ν_{11} band were found to be strongly perturbed. A large number of strong lines (more than 20%) remained unassigned and presumably arose from the perturbing state as well as torsional hot band transitions. The rotational analysis yielded precise spectroscopic constants for the ground vibrational state, which were interpreted in terms of a planar centrosymmetric dimer with a N—N bond length of $1.756(10)\text{ \AA}$.

It is possible that some payloads (satellites or space probes) may become contaminated if bipropellant thrusters used for orbit insertion, midcourse correction, or attitude control have a dribble volume of unreacted NTO. NTO vapors might condense on cold parts of the spacecraft, where they change the albedo, fog up camera lenses, or put a curtain on solar cells. Infrared spectra of frozen NTO and other propellants were measured to better understand the hazards of frozen NTO contamination [172].

The spectrum of a molecular beam of N_2O_4 has been obtained in the 3.2, 5.7, 7.9, and 13.3- μm regions, using a supersonic slit jet system coupled to a Fourier transform spectrometer with a spectral resolution of 0.005 cm^{-1} [173]. Analysis of the spectra obtained indicated that the temperature of the expanding molecular beam is close to 30 K. In the three lowest-frequency spectral regions, not only were the ν_9 , ν_{11} , and ν_{12} fundamental bands observed, but each fundamental was accompanied by an intense combination band that appeared because of a strong anharmonic resonance leading to a transfer of intensity from the fundamental band to the combination band. In the 13.3- μm region, two a-type bands with nearly equal intensities were seen. All of the bands were successfully analyzed, leading to ground-state combination differences that were combined with those obtained in a previous diode laser study and fitted to obtain ground-state rotational constants. The upper-state energy levels were fitted using a Hamiltonian, which explicitly took into account the anharmonic resonances.

FTIR spectra of NO and NO_2 are used for the analysis of NO in MON [174].

3.16.2 Raman Spectra of Dinitrogen Tetroxide

3.16.2.1 Raman Spectra of Liquid Dinitrogen Tetroxide

The Raman spectra of liquid N_2O_4 have been measured at 262, 279, and 297 K [144]. The rotational relaxation rate was found to increase with increasing temperature, and spectra were analyzed qualitatively in terms of two models of vibrational dephasing that took into account the effect of vibrational anharmonicity.

Isotope substitution enables one to assign some of the Raman bands to specific molecular vibrations [162].

3.16.2.2 Raman Spectra of Frozen Dinitrogen Tetroxide

Raman and IR spectra of polycrystalline samples of N_2O_4 at low temperatures were recorded, and the number and activities of the fundamentals were compared with the predictions of group theory, based on known molecular and crystal geometries [175]. Several additional peaks were observed and attributed to Fermi resonances of combinations with fundamentals. A new low-frequency internal mode and five lattice modes were found that are unique to the solid and were not seen in the liquid.

In Raman spectra of frozen N_2O_4 in a matrix of frozen Ne at 9 K, most lines could be assigned to different configurations of N_2O_4 . However, the most intense line was caused by NO^+ ions of the species NO^+NO_3^- , a surprising result explainable by a special aggregation of NO_2 molecules during condensation, followed by trapping of the dimer at adjacent vacancies [176].

Raman spectra of solid N_2O_4 condensed from gaseous $\text{NO}_2/\text{N}_2\text{O}_4$ showed that the $\text{O}_2\text{N}-\text{NO}_2$ dimer was formed at 80 K [177]. Deposition at 15 K additionally produced bands of the NO_2 monomer and the O_2NONO isomers. Warming to 180 K induced autoionization to NO^+NO_3^- , which remained stable over the 15–180 K range. It was sug-

gested that the transition is probably an intermolecular process invoked through the low-energy lattice modes or ν_4 twist vibration of the dimer.

For nitrosonium nitrate, produced by slow NO_2 deposition, three solid modifications (two crystalline, one amorphous) could be characterized spectroscopically by Raman spectra [178]. In the amorphous phase, a light-induced, temperature-dependent, reversible transition between molecular and ionic nitrogen tetroxide is observed below 150 K.

3.16.2.3 Raman Spectra of Dinitrogen Tetroxide Solutions

When the Raman spectra of solutions of dinitrogen tetroxide in nitric acid were recorded, it was noted that the spectrum of the dinitrogen tetroxide molecule was completely absent [159]. The strongest appearances, apart from solvent lines, were a line at 2240 cm^{-1} , which could belong only to the nitrosonium ion in some form, and one at 1050 cm^{-1} , which was identified as the main nitrate ion frequency. The latter constitutes an intensification of one of the self-ionization frequencies of the nitric acid solvent; consistently, its development is accompanied by a disappearance of the other self-ionization line, 1400 cm^{-1} , belonging to the nitronium ion. The solute spectrum also contained a somewhat weak frequency 1380 cm^{-1} , which was assumed to be the totally symmetric fundamental of the nitrogen dioxide molecule, a frequency usually observed only as a weak band in the infrared. It was concluded that the dinitrogen tetroxide molecule, in dilute solution in nitric acid, is almost completely disassociated, partly homolytically, but chiefly heterolytically, as follows:

The frequency of the nitrosonium ion is usually found at about 2300 cm^{-1} , though the value can vary a little with the conditions of solvation. The line at 2240 cm^{-1} , obtained in nitric acid, is, however, outside the usual range of variation, and it was shown to arise from a modification of the nitrosonium ion by some specific molecular interaction. The modifying agent was identified as the nitrogen dioxide molecule. It is assumed to form a molecular compound $\text{NO}^+\bullet\text{NO}_2$, held together by a partly homopolar, but mainly electrostatic, one-electron bond.

3.16.3 Ultraviolet-Visible Spectra of Dinitrogen Tetroxide

Pure liquid dinitrogen tetroxide is a colorless liquid that does not absorb light in the visible range. However, its dissociation product nitrogen dioxide, being a free radical, has an intense reddish-brown color in the gaseous state, which is what gives the distinctive brown color to smog and haze hanging over densely populated cities when the wind is not blowing it away. The absorption spectra of nitrogen dioxide will be discussed in *Encyclopedia of Oxidizers*, chapter "Nitrogen Dioxide."

The individual absorption coefficient curves of NO_2 and N_2O_4 were separated by means of a mechanical analog differential analyzer in the range of 2400–5000 Å, showing the apparently continuous nature of the N_2O_4 absorption [179].

A study of the temperature dependence of the ultraviolet (UV)-visible absorption cross sections for NO_2 has been made in the temperature range of 213–298 K and between 310 and 570 nm using a diode array spectrometer [180]. Analysis of the experimental data allowed the simultaneous measurement of the NO_2 and N_2O_4 cross-sections and the equilibrium constant for the dimerization of NO_2 . Values of cross-sections for N_2O_4 and equilibrium constant for the association of NO_2 were presented in the range of 213–263 K. No temperature effect was observed on the overall shape of the NO_2 absorption spectrum or on the averaged cross-section values used for calculating atmospheric photolysis rates. Changes in the fine structure of the NO_2 spectrum with temperature were observed, and this has important implications for measurements of atmospheric NO_2 made by UV-visible absorption techniques.

3.17 Electron Spin Resonance and Electron Paramagnetic Resonance Studies of Dinitrogen Tetroxide

The homolytic dissociation constants K_{diss} of dinitrogen tetroxide in organic solvents were determined by electron paramagnetic resonance (EPR) measurements [181]. The values are the highest in non-donor and the lowest in n-donor solvents. The variations of K_{diss} with the type of solvent were interpreted in terms of electron donor-acceptor interactions between dinitrogen tetroxide and electron donor solvent molecules.

3.18 Photoelectron Spectroscopic Studies of Dinitrogen Tetroxide

Rapid expansion of vapor through a nozzle inlet system has been used for the study of X-ray photoelectron spectroscopy (XPS) spectra of some molecular species normally only present at pressures much above those usually obtained at the ionization region of a photoelectron spectrometer [182]. The He I photoelectron spectra for dinitrogen tetroxide and dinitrogen pentoxide obtained in this way were compared to Gaussian *ab initio* molecular orbital calculations and the spectra of the dissociated species, also in relation to nitric acid.

Photoelectron spectra excited with a He I line source were measured for a mixture of NO_2 and N_2O_4 in the gas phase at a temperature of about 213 K (–60 °C) [183]. Some photoelectron bands attributable to N_2O_4 were observed below about 16 eV.

3.19 Index of Refraction of Dinitrogen Tetroxide

The index of refraction of liquid dinitrogen tetroxide at 293 K (20 °C) was measured at four different wavelengths, as shown in Table 24.

Table 24: Index of refraction of liquid dinitrogen tetroxide.

Wavelength, Å	Spectral line source	Index of refraction
6893	Sodium	1.420
4916.4	Hg blue-green	1.431
5460.7	Hg green	1.424
4358.3	Hg blue	1.442

Data source: [184]

The refractive index of a thin layer of frozen dinitrogen tetroxide on a silicon substrate at 16 K at 543 nm is 1.316 [185]. At 60 K, the refractive index of frozen dinitrogen tetroxide at 543 nm is 1.548, and its density is 1.90 g/cm³. The refractive index of liquid N₂O₄ at 300 K at 543 nm is 1.40. This work also contains infrared spectra of NO₂/N₂O₄ equilibrium mixtures flash-frozen on a sample holder at 16 or 60 K.

3.20 Electrical Properties of Dinitrogen Tetroxide

3.20.1 Dielectric Constant of Dinitrogen Tetroxide

The relative permittivity of a material for a frequency of zero is known as its *static relative permittivity* or *specific inductance capacity* or *dielectric constant*. The dielectric constant ϵ is a dimensionless quantity but is definable in terms of capacitance:

$$\epsilon = \frac{C}{C_0}$$

where ϵ = dielectric constant, C = capacitance of a capacitor when the spaces between the plates are occupied by a given dielectric, and C_0 = capacitance of same capacitor *in vacuo*.

The dielectric constant of N₂O₄ was determined by comparing the capacity of a specially prepared capacitor at 1000 Hz in air and in liquid N₂O₄. The dielectric constant of liquid N₂O₄ has been found to be 2.42 at 18 °C [184]. When the temperature of the sample was reduced from 291 K (18 °C) to 268 K (−5 °C), the dielectric constant did not change much. Earlier investigators had reported 2.56 (at 15 °C) and 2.6 (at −40 °C) for the dielectric constant of N₂O₄.

The relative permittivity and electrolytic conductivity of N₂O₃, N₂O₄, and their mixtures have been measured over a range of temperatures limited by the freezing

point of the system on the one hand and its vapor pressure on the other [186]. The results for N_2O_4 are presented in Table 25. The values of relative permittivity ϵ N_2O_4 are typical for a non-polar liquid and showed little variation with temperature.

Table 25: Electrical physical properties of dinitrogen tetroxide.

Temperature, K	293	283	273	263	253
Temperature, °C	+20	+10	0	−10	−20
Relative permittivity ϵ N_2O_4	2.44	2.45	2.47	2.48	2.49
Molar polarization P , $\text{cm}^3 \text{mol}^{-1}$	20.6	20.4	20.3	20.1	19.9
Electrolytic conductivity $\lambda \times 10^{12}$, $\Omega^{-1} \text{cm}^{-1}$	5.03	3.32	2.18	1.38	0.84

Data source: [186]

Since N_2O_4 has a symmetric structure in the gas and solid, it is unlikely to possess a permanent dipole moment in the liquid. Although NO_2 is a polar molecule, its concentration in the N_2O_4 liquid is far too low to account for such a large temperature variation. The same applies to other possible species such as NO^+ and NO_3^- in the form of ion-pairs or solvated ions.

Liquid propellant-level gauging in a rotating spacecraft can be achieved by capacitance measurements of the liquid-filled space between two concentric tubes serving as the electrodes of a capacitor. Dielectric properties (permittivity and specific conductivity) of MON-1 and MMH were measured as a function of temperature because these numbers were needed for calibrating the sensors [187, 188]. The relative permittivity of MON-1 between 283 and 323 K can be expressed by the following equation:

$$\epsilon = 2.833 - 0.0052 \times (T - 273)$$

where ϵ is the relative permittivity (a dimensionless number) and T is the temperature in kelvin.

3.20.2 Electrical Conductivity of Dinitrogen Tetroxide

When the electrical conductivity of several batches of N_2O_4 prepared by decomposition of lead(IV) nitrate was compared, it was noted that there was a slight variation in conductivity from one preparation to another, which, in view of the extremely low order of conductivity, was unavoidable. The drying system employed in the preparation of the dinitrogen tetroxide was efficient, since further redistillation through phosphoric oxide desiccant did not decrease the conductivity any further. The most reliable value of the electrical conductivity of liquid dinitrogen tetroxide was $1.3 \times 10^{-12} \text{ ohm}^{-1} \text{cm}^{-1}$ at 290 K (17 °C) [189] (Table 26).

Other sources reported a specific conductivity of $3.0 \times 10^{-13} \text{ ohm}^{-1} \text{cm}^{-1}$ at 297 K (24 °C). These values indicate that the concentration of ionic species in the pure liquid is extremely small. A different sample was measured at several temperatures between

Table 26: Specific electrical conductivity of N_2O_4 as a function of temperature

Temperature		$\lambda \times 10^8$
K	°C	$\text{ohm}^{-1} \text{cm}^{-1}$
263	-10	1.16
273	0	7.83
283	+10	9.75
293	20	14.2
303	30	17.6

Data source: [190, 191]

280.4 K (7.3 °C) and 293.5 K (20.4 °C), and the electrical conductivity increased almost linearly from 1.17×10^{-12} to $2.24 \times 10^{-12} \text{ohm}^{-1} \text{cm}^{-1}$ with a temperature coefficient of $8.5 \times 10^{-14} \text{ohm}^{-1} \text{cm}^{-1} \text{°C}^{-1}$. The low electrical conductivity in liquid dinitrogen tetroxide may arise from either ionic or electronic conduction. If conduction is ionic, the low conductivity value indicates that the number of free ions is extremely small, and this is consistent with the low value observed for the dielectric constant. The positive temperature coefficient may be a result of the increase in homolytic dissociation

with temperature.

The addition of water increased the electrical conductivity of commercial-grade N_2O_4 substantially, from $1.88 \times 10^{-6} \text{ohm}^{-1} \text{cm}^{-1}$ at 1% H_2O addition to $4.52 \times 10^{-2} \text{ohm}^{-1} \text{cm}^{-1}$ at 14% H_2O [192]; see Table 27.

Table 27: Electrical conductivity in the $\text{N}_2\text{O}_4/\text{H}_2\text{O}$ system.

Added H_2O Volume-%	Resistance ohm	Specific conductivity $\text{ohm}^{-1} \text{cm}^{-1}$
1.0	4.20×10^5	1.88×10^{-6}
2.0	3.50×10^5	2.6×10^{-6}
3.0	4.22×10^5	1.86×10^{-6}
5.0	4.16×10^5	1.90×10^{-6}
10.0	5.03×10^5	1.57×10^{-6}

3.21 Magnetic Properties of Dinitrogen Tetroxide

NO_2 gas is paramagnetic, and frozen N_2O_4 is diamagnetic. The molecular susceptibility of frozen N_2O_4 is $\chi = -30 \times 10^{-6}$ cgs units. The paramagnetism of NO_2 was used to determine its concentration in an equilibrium mixture of dissociating pure N_2O_4 . The magnetic susceptibility of pure liquid N_2O_4 was measured by the Gouy method over the temperature range 273–303 K (0–30 °C) [193]. The liquid was found to be diamagnetic throughout this temperature range, although the diamagnetism decreased as the temperature increased. The magnetic measurements were found to be in good agreement with the spectrophotometrically determined equilibrium composition of the liquid, as reported earlier [194].

Nuclear magnetic resonance (NMR) can also be used for the rapid quantitative analysis of water (mostly in the form of nitric acid) in dinitrogen tetroxide and MON oxidizers [195].

4 Physical Properties of Oxidizer Blends with Dinitrogen Tetroxide

For some space mission applications, in particular those in the shadow of the Earth or at great distances from the sun, the relatively high freezing point of dinitrogen tetroxide, 262 K (−11 °C), is a disadvantage. Some space missions involve long cruising periods when not much energy is available to heat the tank to prevent the propellants from freezing. There have been numerous attempts to identify additives to N_2O_4 that will lower its freezing point without unduly increasing the vapor pressure or reducing its rocket performance.

4.1 $\text{N}_2\text{O}_4/\text{N}_2\text{O}_3$ Mixtures

The most successful additive for lowering the freezing point of dinitrogen tetroxide is dinitrogen trioxide, N_2O_3 . Dinitrogen trioxide is not added as such, but instead the pure dinitrogen tetroxide is doped with nitric oxide, NO, which is added as a gas. The reaction taking place in the liquid phase is

and the solution turns from colorless or slightly yellow to blue. This reaction is exo-endo-thermic, depending on the direction in which it proceeds. Little to no NO exists in the liquid phase of the MON system. One can assume that the liquid phase contains only N_2O_3 and N_2O_4 .

The mixtures of N_2O_3 with N_2O_4 could have been discussed at the N_2O_3 chapter (*Encyclopedia of Oxidizers*, chapter “Dinitrogen Trioxide”) or here in the N_2O_4 section. We preferred to describe the mixtures here because the major constituent of the practically used $\text{N}_2\text{O}_3/\text{N}_2\text{O}_4$ mixtures is N_2O_4 and not N_2O_3 .

Dinitrogen trioxide and dinitrogen tetroxide are completely miscible in all proportions over their entire range of mixture ratios.

Blends of N_2O_4 with N_2O_3 are called “**mixed oxides of nitrogen**,” abbreviated as MON. The designation MON is often followed by a number, such as MON-3 or MON-25, which indicates the mass (weight) percent of NO (not the mass-percent of N_2O_3) in the mixture. The MIL-SPEC MIL-PRF-26539F on MON describes this type of oxidizer as having a green color. It is a sort of blue-green. Specification requirements for these different grades of oxidizers are described in Table 41.

Small amounts of MON (50 mL) with NO mass concentrations between 0 and 30% NO can be prepared from $\text{N}_2\text{O}_4(\text{L})$ and $\text{NO}(\text{G})$ feedstocks in a glass apparatus at low pressures [196]. The glass tube was rated to a safe operating pressure of 1.03 MPa (150 psi) gauge, which allowed for synthesis of MON-30 at 273 K without risk of overpressurization. Using a glass vessel for synthesis allows for visual monitoring of reactant loading and mixing, which is a convenient feature considering the significant color change that accompanies the dissolution of NO into N_2O_4 . The contents of the glass tube were weighed before and after the addition of N_2O_4 and NO. The N_2O_4 had to be stirred during NO addition. The measured quantity of NO gas was coming from a buffer tank with known volume and pressure. For higher MON-X mixtures, several buffer tank loads had to be added. Vapor pressure readings on the freshly prepared MON-13 samples ran high because of inert gases introduced with the NO. The final NO composition of samples prepared using this setup could be confirmed by observing the mass (and color) change of the sample following complete oxidation of the NO in the system by pressurizing it with oxygen in the same apparatus.

The U.S. Defense Logistics Agency at its website [197] lists the available grades of NTO and MON as MON-1, MON-3, MON-10, and MON-25 in addition to bulk NTO. The price is the same for all grades. All grades of NTO or MON are substantially more expensive than inhibited red fuming nitric acid (IRFNA).

MON-10 is typically used to increase the NO content of MON-1 or MON-3 that has fallen below specification levels (NO is preferentially lost from MON during transfer operations). Occasionally, a program may require the low-temperature freezing point quality of MON-10 versus the other grades, but this requirement is usually limited to tactical missile systems or interplanetary missions.

One of the first flight applications of MON-10 oxidizer was in the MIRA-150A throttleable engine that powered the first unmanned lunar landers Surveyor 1 through 7 [198]. The reason for selecting MON-10 instead of pure NTO was to lower the freezing point of NTO. At the same time, instead of pure MMH, a mixture of MMH

and 28% water was used instead of pure MMH as the fuel to facilitate cooling of the engine.

As explained in the chapter on pure dinitrogen trioxide, N_2O_3 begins to decompose reversibly into nitric oxide and nitrogen dioxide (dinitrogen tetroxide) at temperatures above 173 K (-100°C) [199]. The presence of dinitrogen tetroxide, one of the decomposition products, should retard the decomposition in accordance with the law of mass action, but it does not prevent it altogether.

In the liquid phase there is an equilibrium between nitric oxide and nitrogen dioxide and between nitrogen dioxide and dinitrogen tetroxide:

The addition of nitric oxide (dinitrogen trioxide) to N_2O_4 in quantities exceeding 3% NO has several potential disadvantages, and the amount of additive has to be optimized depending on the intended application:

- increased vapor pressure
- reduced available oxygen content
- reduced enthalpy of formation
- extended ignition delay with hypergolic fuels
- possible change in composition of propellant as the result of repeated transfers or pressurant venting
- decreased density

A mixture consisting of 70 mass-% N_2O_4 and 30 mass-% NO contains only 64.7 mass-% oxygen, whereas pure N_2O_4 contains 69.6% oxygen.

The physical properties of the binary system $\text{N}_2\text{O}_3/\text{N}_2\text{O}_4$ have been thoroughly measured in view of the various applications as rocket propellants. Temperature gradients in a compartmented system filled with MON-25 might result in composition gradients. An excellent summary of properties of MON and methods for analysis of MON was provided in [200], with emphasis on MON-25.

4.1.1 Freezing Point and Phase Diagram of $\text{N}_2\text{O}_4/\text{N}_2\text{O}_3$ Mixtures

The freezing points of mixtures of dinitrogen tetroxide and dinitrogen trioxide, as well as those of the pure components, have been accurately determined [23]. Although the phase diagram (Figure 27) has the appearance of a simple binary mixture with one eutectic, it seems probable that, on the nitrogen dioxide-rich side of the composition range, solid solutions crystallize rather than the pure component. A possible misinterpretation of previous results in the region of the eutectic composition would account for the discrepancy between the eutectic temperature and composition compared with

previously accepted values. Dinitrogen trioxide behaves as a pure compound at its freezing point. The following data have been recorded: freezing point of dinitrogen tetroxide, 261.86 K (−11.29 °C); eutectic composition, 33.7 mass-% of nitric oxide; eutectic temperature, 166.95 K (−106.2 °C); and freezing point of dinitrogen trioxide, 172.45 K (−100.7 °C). The Beattie, Bell, and Vosper [24] results are presented in Table 28 and Figure 27.

Figure 27: Freezing-point diagram of the $\text{NO}/\text{NO}_2=\text{N}_2\text{O}_3/\text{N}_2\text{O}_4$ system. (Reprinted and modified from [24]. Reprinted with permission from © 1960 The Royal Society of Chemistry.)

Additional data on physical properties of $\text{NO}/\text{NO}_2=\text{N}_2\text{O}_3/\text{N}_2\text{O}_4$ mixtures are available in [23, 201, 202].

As illustrated in Figure 27, the freezing point of the binary system $\text{N}_2\text{O}_3/\text{N}_2\text{O}_4$ passes through a minimum and then gradually increases to the value for pure N_2O_3 (171 K [−102 °C]) [203]. MON-25 begins to separate into two phases and N_2O_4 crystals precipitate below 233 K (40 °C) [204].

The triple point of MON-2.2 was determined using two different methods [205]. The first method used a glass apparatus in the laboratory. In the second method, the fluid was exposed to a specific pressure in a very large vacuum chamber and was allowed to cool by evaporation to the equilibrium temperature for the fluid at the pressure exerted. This method simulated a space-like environment to allow more proper evaluation of the behavior of propellants when exposed to the near vacuum of space if a leak should occur in the tankage and feed system. Tentative values for the effective freezing point under space-like conditions of MON containing 2.2 mass-% nitric oxide were determined to be 259.4 K (7.2 °F) at 15.444 pascals (2.24 psia). This value differed con-

Table 28: Freezing points in the $\text{NO}/\text{NO}_2=\text{N}_2\text{O}_3/\text{N}_2\text{O}_4$ system.

siderably from the triple-point values of 261.9 K (11.73 °F) at 18.637 pascals (2.703 psia) determined using the 1938 laboratory triple-point technique on NTO containing little or no nitric oxide.

4.1.2 Boiling Point of $\text{N}_2\text{O}_4/\text{N}_2\text{O}_3$ Mixtures

The graph shown in Figure 28 was composed by Beattie and Vosper ([206], part III), who collected boiling-point data of $\text{N}_2\text{O}_3/\text{N}_2\text{O}_4$ mixtures from several sources and compared them to their own measurements.

Figure 28: Boiling-point data of $\text{N}_2\text{O}_3/\text{N}_2\text{O}_4$ mixtures from several sources. (Reprinted and modified from [206], part III. Reprinted with permission from © 1960 The Royal Society of Chemistry.)

4.1.3 Vapor Pressure of $\text{N}_2\text{O}_4/\text{N}_2\text{O}_3$ Mixtures

The vapor pressure of mixtures of nitrogen dioxide and nitric oxide has been measured by several investigators at various temperatures. One set of results can be expressed by

$$\log_{10} p = 8.95 - f \frac{(x)}{T}$$

where p is the pressure in mm Hg, T is the temperature in kelvin, and $f(x)$ is a function dependent only on the composition of the mixture [206]. Extrapolating from those data, the apparent boiling point of dinitrogen trioxide would be at least 40° below the previously accepted value. Low-temperature vapor pressure data indicate that Giauque and Kemp's equation for nitrogen dioxide can be extrapolated down to about 223 K (-50°C). The only more recent work on the vapor pressure of mixtures of nitric oxide and nitrogen dioxide at pressures below 1 atm is that of Whittaker and colleagues [23]. Unfortunately, their results do not extend beyond the region near nitrogen dioxide, where they are in reasonable agreement with those ancient data of Baume and Robert. The data of Baume and Robert cover the whole range of compositions from nitrogen dioxide to dinitrogen trioxide but do not extend below 253 K (-20°C), and in this region agreement with Purcell and Cheesman's results [207] is poor. Further, in the latter paper only "smoothed" results are given, which lie very erratically on a graph of $\log_{10}$ (pressure) against the reciprocal of the absolute temperature.

The vapor pressure isotherms graph (Figure 29) was composed by Beattie and Vosper ([206], part III), in which they collected the vapor pressure of $\text{N}_2\text{O}_3/\text{N}_2\text{O}_4$ mixtures from several sources and compared them to their own measurements.

Figure 29: Vapor pressure isotherms of $\text{N}_2\text{O}_3/\text{N}_2\text{O}_4$ mixtures. (Reprinted and modified from [206]. Reprinted with permission from © 1960 The Royal Society of Chemistry.)

Measured vapor pressures of $\text{N}_2\text{O}_3/\text{N}_2\text{O}_4$ mixtures over the range of 0–16.95 mass-% NO at temperatures from 288 to 313 K (15–40 °C) can be curve-fitted and expressed as a set of equations, each valid for a narrow temperature range, as shown in Table 29 [23].

Table 29: Vapor pressure equations of NO/ $\text{N}_2\text{O}_3/\text{N}_2\text{O}_4$ mixtures.

Mass-% NO	Temperature range, °C	P_V equation*, torr	Mean error, ±torr
2.89	+15 to -14.1	$\log P_V = 9.0121 - 1782.2/T$	2.8
5.55	+15 to -17.1	$\log P_V = 8.9700 - 1751.3/T$	2.3
8.30	+15 to -20.4	$\log P_V = 9.0105 - 1745.3/T$	1.4

14.11	+2 to -28.8	$\log P_V = 8.9847 - 1704.6/T$	2.2
16.85	+5 to -33.6	$\log P_V = 9.0347 - 1702.4/T$	1.8

* P_V is the vapor pressure in mm Hg, and T is the temperature in kelvin

Data source: [23]

Most of the work on MON mixtures has been done with MON-1 and MON-3. Thus, it is very useful to find some older data on the physical properties of MON mixtures with higher NO contents in the range of 20–30 mass-% NO. The raw vapor pressure data

from which the curves in Figure 30 were generated originated in a 1954 report from Food Machinery and Chemical Corporation [3]. The measured vapor pressures of three MON mixtures are tabulated in Table 30 and graphed in Figure 30. The curves for 28.5 and 29.2 mass-% NO overlap.

Data source: [3]

Figure 30: Vapor pressure of mixed oxides of nitrogen. (Chart created by Schmidt 2016, based on data from [3].)

Data in a later publication by the same author giving data for NO concentrations up to 30 mass-% NO are based on the earlier WADC report cited earlier [203] (Figure 31).

Figure 31: Vapor pressure of the system $\text{N}_2\text{O}_3/\text{N}_2\text{O}_4$. (Reproduced and modified from [3].)

Vapor pressure measurements of samples of MON containing 1.69, 2.10, or 2.98 mass-% NO indicated that the actual vapor pressure is 13.8–34 kPa (2–5 psia) higher than that listed in the *Nitric Acid/Nitrogen Tetroxide Oxidizers Handbook* (AFRL-TR-76-76) for any given temperature [208].

The vapor pressures of MON-10, MON-25, and MON-30 can be calculated from the equations listed in Table 31.

Table 31: Equations for vapor pressure of MON-10, MON-25, and MON-30.

MON-	Vapor pressure equation*	Lower <i>T</i>		Upper <i>T</i>	
		K	°F	K	°F
10	$\log_{10}P = 7.4956 - 1352.4/T - 56662/T^2$	250.2	-9.3	405.2	270
25	$\log_{10}P = 7.4956 - 1236.0/T - 56662/T^2$	219.2	-65	405.2	270

**P* is the pressure in kPa, and *T* is the temperature in kelvin

Data source: [209]

4.1.4 Density of N₂O₄/N₂O₃ Mixtures

The density of the N₂O₄/N₂O₃ mixtures decreases with increasing NO content (Figure 32).

Figure 32: Density of N₂O₃/N₂O₄ mixtures as a function of temperature. (Reproduced and modified from [3].)

Figure 33 presents the same density data in a different format as a function on NO content rather than as a function of temperature.

Figure 33: Density of $\text{N}_2\text{O}_3/\text{N}_2\text{O}_4$ mixtures as a function of NO content. (Reproduced and modified from [3].)

Density measurements were conducted on a MON-1 composition containing 1.17 mass-% NO and 0.07 mass-% H_2O over the temperature range 295.4–347.3 K (22.3–74.2°C; 72.1–165.6°F). A total of 16 individual data points were generated from two measurement sets using a Poole-Nyberg densimeter. A least-squares curve-fit of the data resulted in the following expression of density as a function of temperature [35]:

$$\rho = 1.4883 - 2.180 \times 10^{-3}t - 4.109 \times 10^{-6}t^2$$

where ρ is the density in g/cm^3 and t is the temperature in °C. The standard error estimate was $\pm 0.001 \text{ g}/\text{cm}^3$. For mixtures with varying NO content, the density of MON as a function of temperature from 279.3 to 351.3 K (6.2–78.2°C; 43.1–172.8°F) and composition (0–1.17 mass-% NO) can be calculated from

$$\begin{aligned} \rho = & 1.4901 - 1.80169 \times 10^{-3}t - 2.71835 \times 10^{-5}t^2 + 5.093 \times 10^{-7}t^3 - 3.614 \times 10^{-9}t^4 \\ & - 2.9839 \times 10^{-3}N \end{aligned}$$

where ρ is the density in g/cm^3 , t is the temperature in °C, and N is the concentration of NO in mass-%. The effect of a trace of water within the specification range of 0–

0.17 mass-% H_2O was negligible. For higher NO contents, the following equation was derived for temperatures from freezing points to 378 K (105 °C) and NO contents from 0 mass-% NO to 30 mass-% NO:

$$\rho = 1.4905 - 2.124 \times 10^{-3}t - 5.01 \times 10^{-6}t^2 - 3.250 \times 10^{-3}N + 1.804 \times 10^{-5}N^2 \\ + 1.458 \times 10^{-5}Nt + 3.852 \times 10^{-7}N^2t - 2.226 \times 10^{-7}Nt^2$$

where ρ is the density in g/cm^3 , t is the temperature in °C, and N is the concentration of NO in mass-%.

The density of MON-10 as a function of temperature for a temperature range of 250.2–378.2 K (–9.3 to 221 °F) can be calculated from

$$\rho_L = 1.465 - 2.14 \times 10^{-3}(T - 273.2) - 6.26 \times 10^{-6}(T - 273.2)^2$$

where ρ_L is the liquid density of MON-10 in g/cm^3 and T is the temperature in kelvin. The density of MON-25 between 219.2 K (–65 °F) and 378.2 K (221 °F) can be calculated from

$$\rho_L = 1.436 - 2.16 \times 10^{-3}(T - 273.2) - 4.80 \times 10^{-6}(T - 273.2)^2$$

where ρ_L is the liquid density of MON-25 in g/cm^3 and T is the temperature in kelvin. Likewise, the density of MON-30 between 192.2 K (–114 °F) and 378.2 K (221 °F) can be calculated from

$$\rho_L = 1.425 - 2.07 \times 10^{-3}(T - 273.2) - 4.31 \times 10^{-6}(T - 273.2)^2$$

where ρ_L is the liquid density of MON-30 in g/cm^3 and T is the temperature in kelvin.

Results of measurements of the volumetric behavior of $\text{N}_2\text{O}_3/\text{N}_2\text{O}_4$ mixtures under a wide range of different conditions are reported in [210].

A very thorough and critical review of literature data on the density of MON mixtures as a function of NO content, temperature, and pressure was conducted to determine the accuracy of the empirical fit for the liquid density of MON oxidizers [211]. The data of Pascal and Garnier [212] cited therein were found to disagree with data in McGonigle [213] and Brice [3] for MON blends with higher NO content. The data of Pascal and Garnier for NO content of 12, 20, and 30 mass-% were omitted from the data set. Several of the older literature sources cited in that publication are not easily accessible, in particular [212, 213]. The compilation of literature data from numerous sources deemed to be reliable was fitted with a useful polynomial equation for the density of MON:

$$\rho = 1689.3 + 0.61408T - 4.9261 \times 10^{-3}T^2 - 2.4615W$$

where ρ is the density in kg/m^3 , T is the temperature in kelvin, and W is the NO content in mass-%. The density as a function of temperature, pressure, and NO content can be calculated from the equation

$$\rho = 1689.3 + 0.61408T - 4.9261 \times 10^{-3}T^2 - 2.4615W + 1.6 \times 10^{-3} \cdot (P - P_{\text{vap}})$$

where ρ is the density in kg/m^3 , T is the temperature in kelvin, W is the NO content in mass-%, and P is the pressure in kPa.

A Poole-Nyberg densimeter was modified to measure density data for MON over a wider range of NO contents up to 30% NO between 193 K (-80°C) and 323 K (50°C) and higher pressures up to 6.8 MPa [214]. In order to check the apparatus, the density of pure NTO was measured at first from 263 K (-10°C) to 323 K (50°C) for pressures between 207 and 620 kPa (30 and 90 psia, respectively) and compared to literature data. With this measurement technique, the density of NTO at 293 K (20°C) was obtained with an estimated deviation from literature data of less than 0.2%, with larger deviations at higher temperatures. Subsequent measurements for MON-10 did not give the expected results. The density of frozen N_2O_3 at 78 K is 1.782 g/cm^3 [37].

4.1.5 Viscosity of $\text{N}_2\text{O}_4/\text{N}_2\text{O}_3$ Mixtures

The viscosity of $\text{N}_2\text{O}_3/\text{N}_2\text{O}_4$ mixtures varies only moderately with varying NO content of $\text{N}_2\text{O}_3/\text{N}_2\text{O}_4$ mixtures [203, 215]. Figure 34 gives the dynamic viscosity as a function of temperature for four different $\text{N}_2\text{O}_3/\text{N}_2\text{O}_4$ mixtures.

Figure 34: Dynamic viscosity of $\text{N}_2\text{O}_3/\text{N}_2\text{O}_4$ mixtures. (Reproduced and modified from [3].)

The viscosity of a mixture containing 8 mass-% N_2O_3 /92% N_2O_4 is shown in Figure 35 as a function of temperature and pressure.

Figure 35: Viscosity of $\text{NO}/\text{N}_2\text{O}_4$ mixture containing 92 mass-% N_2O_4 . (Reprinted and modified from [215], with permission from © 1954 American Chemical Society.)

The viscosities of MON-10, MON-25, and MON-30 can be calculated from the equations listed in Table 32.

Table 32: Equations for viscosity of MON-10, MON-25, and MON-30.

MON- Viscosity ^a		Lower <i>T</i>		Upper <i>T</i>	
		K	°F	K	°F
10	$\mu = -0.03148 + 28.143/T - 8.569 \times 10^3/T^2 + 9.822 \times 10^5/T^3$	277.2	39.3	377.2	219
25	$\mu = -0.0335 + 28.876/T - 8.569 \times 10^3/T^2 + 9.822 \times 10^5/T^3$	277.2	39	377.2	219
30	$\mu = -0.03463 + 29.376/T - 8.569 \times 10^3/T^2 + 9.822 \times 10^5/T^3$	278	40.7	378	221

4.1.6 Surface Tension of $\text{N}_2\text{O}_4/\text{N}_2\text{O}_3$ Mixtures

Surface tension does not change significantly as the result of adding NO or N_2O_3 to N_2O_4 . For instance, surface tension at 233 K (-40°C) changes only from 37.4 to 39 dyn/cm if the NO concentration is increased from 21 to 28 mass-%, as shown in Figure 36 [3, 203].

Figure 36: Surface tension of $\text{N}_2\text{O}_3/\text{N}_2\text{O}_4$ mixtures. (Reproduced and modified from [3].)

4.1.7 Electrical Properties of $\text{N}_2\text{O}_4/\text{N}_2\text{O}_3$ Mixtures

4.1.7.1 Dipole Moment and Relative Permittivity

For $\text{N}_2\text{O}_4/\text{N}_2\text{O}_3$ mixtures, the relative permittivity increased with the mol fraction of N_2O_3 in a non-linear manner, but the molar polarization increased rapidly at first and then reached an almost constant value (Figure 37) [186]. If one wants to use either of these properties for the analysis of $\text{N}_2\text{O}_4/\text{N}_2\text{O}_3$ mixtures, it would have been better if they showed a linear relationship, or one must restrict the use to lower N_2O_3 concentrations (0.5).

Figure 37: Molar polarization and electrolytic conductivity of $\text{N}_2\text{O}_4/\text{N}_2\text{O}_3$ mixtures at 253 K. (Republished and modified from [186], with permission of © 1974 Royal Society of Chemistry; permission conveyed through Copyright Clearance Center Inc.)

4.1.7.2 Electrical Conductivity of $\text{N}_2\text{O}_4/\text{N}_2\text{O}_3$ Mixtures

The addition of small amounts of N_2O_3 caused a rapid increase in the electrolytic conductivity of N_2O_4 . The electrical conductivity of N_2O_4 is substantially increased by the addition of NO (to form N_2O_3) and/or NOCl, with the former exerting the greater effect. It has been shown that the presence of 10 mol-% N_2O_3 increases the conductivity of N_2O_4 by a factor of 1400, while the presence of an equivalent molar concentration of NOCl increases it by a factor of 350. At a given temperature, the electrolytic conductivity increased with the concentration of N_2O_3 , reaching a maximum at about 90 mol-% N_2O_3 and then decreasing until it reached the value for pure N_2O_3 (Figure 37; note that the right-hand scale in Figure 37 is logarithmic!). The maximum conductivity does not necessarily correspond to the greatest concentration of ions since it also depends on the viscosity of the medium and the ionic mobilities of the ions.

4.1.8 Solubility of Pressurant Gases in $\text{N}_2\text{O}_4/\text{N}_2\text{O}_3$ Mixtures

A bubble-point technique was developed at NASA's WSTF to provide an on-the-spot method for determining when the propellant is saturated with helium [216]. The bubble point, for this application, was defined as the pressure at which gas coming out of solution can be visually detected. For any set of liquid conditions, the bubble point will always occur at some pressure below the pressure at which the liquid is saturated. For MON, the observed bubble point pressures were measured over the pressure range of 689–1930 kPa gauge (100–280 psig). The NO content of the oxidizer was 1.5 mass-%. The average temperature of the oxidizer was 286 K (12.8 °C; 55 °F). These data were ana-

lyzed by a least-squares method to obtain the following equation relating bubble-point pressure as a function of supply tank pressure:

$$P = -8.829432 + 0.933971S$$

where P is the bubble-point pressure in psig and S is the supply tank pressure in psig.

A model was created to simulate the two-phase behavior of MON- x /He mixtures, with x ranging from 0 to 6, and the accuracy of the model predictions was scrutinized by comparison with experimental results [217]. The first tests were performed with pure gas (He and NO) and binary mixtures (N_2O_4 /He, NO_2 /NO, NO/He). Thermodynamic equilibria were studied for the MON-3/He mixture over a temperature range from 273 to 323 K (0–50 °C) at pressures ranging from 0 to 17 bars, with various tank ullage values. Afterward, experimental results were compared with the simulation model predictions. Where deviations were noted, the model was then improved and applied to a bipropellant system of an in-flight satellite in order to calculate the remaining MON mass in the oxidizer from telemetry data.

4.1.9 Thermodynamic Properties of N_2O_4 / N_2O_3 -Mixtures

The heat capacity of N_2O_4 / N_2O_3 mixtures was measured in a calorimeter in comparison to that of well-characterized liquids such as diethyl ether [3]. The heat capacities of four N_2O_4 / N_2O_3 mixtures are listed in Table 33. See also [218].

Table 33: Heat capacities of N_2O_3 / N_2O_4 mixtures.

NO content, mass-%	Heat capacity	
	$\text{cal g}^{-1} \text{ } ^\circ\text{C}^{-1}$	$\text{J g}^{-1} \text{ K}^{-1}$
21.1	0.71	2.97
26.3	0.75	3.14
28.2	0.62	2.59
28.3	0.55	2.30

Data source: [3]

4.1.10 Applications of MON-25 Oxidizers

MON-25/MMH hypergolic combinations are intended for Mars-sample return missions, which have to operate in a very cold environment [200, 219, 220]. Other applications of MON-25 will be discussed in future volumes of this encyclopedia dealing with bipropellant combinations.

4.2 $\text{N}_2\text{O}_4/\text{N}_2\text{O}_5$ Mixtures

At first glance, one would think that mixtures of dinitrogen tetroxide with dinitrogen pentoxide should make even more powerful oxidizers than mixtures of dinitrogen tetroxide with dinitrogen trioxide. For practical and safety reasons, none of these have been examined or even tested.

The oxygen content of N_2O_4 can be improved by the addition of N_2O_5 . Such additions might also lower the freezing point of N_2O_4 in a manner similar to that effected by N_2O_3 . However, dinitrogen pentoxide, the anhydride of nitric acid, is even less stable than nitric acid and slowly decomposes **irreversibly** to lower oxides of nitrogen and free oxygen. If the oxidizer blend is kept cold (close to its freezing point), the storage life could be extended without having to vent the pressure buildup in the tank from oxygen, which dissolves only sparingly in the oxidizer blend.

As illustrated in the melting-point diagram of the $\text{N}_2\text{O}_4/\text{N}_2\text{O}_5$ system in Figure 38, a low-melting eutectic point (257.2 K; -15.8°C) can be achieved with only 10.8 mass-% N_2O_5 , but it is not a significant improvement over the freezing point of pure N_2O_4 [221]. The dashed line indicates areas where the mixtures supercooled without freezing.

Figure 38: Melting-point diagram of the $\text{N}_2\text{O}_4/\text{N}_2\text{O}_5$ system. (Republished and modified from [221], with permission from © 1935 Royal Society of Chemistry; permission conveyed through Copyright Clearance Center Inc.)

Solutions of N_2O_5 in N_2O_4 had a strong tendency to supercool, such that it was difficult to obtain accurate melting points. Solutions of N_2O_5 in N_2O_4 exhibited such remarkable supercooling that it was possible to determine the freezing point of supercooled mixtures far beyond the eutectic temperature. In this way the (metastable) freezing-

point curve was extended from 11 to 30% N_2O_5 , the supercooling then being a ΔT of 24 °C. It was necessary to initiate crystallization by chilling the liquid either in ice or in carbon dioxide snow and acetone, and then shaking the tube or agitating the liquid with an internal stirrer.

The effective freezing-point suppression of N_2O_4 by the addition of N_2O_5 is only minimal, but it may be possible to achieve even lower melting blends by adding a third ingredient, such as HNO_3 or $\text{C}(\text{NO}_2)_4$. It is a prerequisite that the third ingredient must be fully compatible with N_2O_5 , and only a few chemicals do not react with it. Melting-point data of the $\text{N}_2\text{O}_4/\text{N}_2\text{O}_5$ system are listed in Table 34.

Table 34: Melting points of $\text{N}_2\text{O}_4/\text{N}_2\text{O}_5$ mixtures.

Mass-% N_2O_5	Mass-% N_2O_4	Melting point		Supercooling possible down to	
		K	°C	K	°C
4.29	95.71	261.3	−11.8		
8.76	91.24	258.8	−14.3		
11.86	88.14	256.8	−16.3		
16.12	83.88	263.0	−10.1		
19.46	80.54	266.7	−6.4	254.9	−18.2
29.31	70.69	274.2	+1.1	254.0	−19.1
39.86	60.14	281.1	+8.0	249.9	−23.2
50.05	49.95	286.0	+12.9		

Data source: [221]

There is no indication that N_2O_4 and N_2O_5 might form compounds with stoichiometric molar ratios. As long as the mixture is kept painstakingly anhydrous, N_2O_4 and N_2O_5 are miscible over the entire range of mixture ratios. However, in the presence of only a trace of water, phase separation occurs because of the formation of nitric acid.

4.3 $\text{N}_2\text{O}_4/\text{N}_2\text{O}$ Mixtures

If nitrous oxide is bubbled into a cooled sample of N_2O_4 kept in an ice bath with a salt/ice mixture, a partially saturated solution will contain 9.5% N_2O and will have a freezing point of 255.7 K (−174 °C) and a boiling point of 301 K (28 °C) [222]. In a similar test, where it was observed that N_2O bubbles bubbling through cooled N_2O_4 were completely absorbed before they reached the surface, the saturated solution contained 41.5 mass-% N_2O and had a freezing point of 222 K (−51 °C) and a boiling point of 306 K (33 °C). The absorption of N_2O into N_2O_4 was exothermic, suggesting that some sort of chemical reaction may have taken place in addition to forming a physical solution. Many years later, propellant combinations with mixtures of N_2O and N_2O_4 containing

between 28 and 52 mass-% N_2O_4 were again patented [223], but there was no reference to prior art such as [222].

4.4 Mixtures of Dinitrogen Tetroxide with Nitro Compounds

Dinitrogen tetroxide dissolves readily in many organic nitro compounds, e.g., nitromethane, nitroethane, and nitrobenzene, without reaction. However, such mixtures must be handled with extreme caution because they are shock sensitive and are very powerful explosives, comparable in sensitivity and power to glycerol trinitrate. Binary mixtures of dinitrogen tetroxide and benzene have been used in bombs, in which the components were mixed in mid-air only after the bomb was dropped from the bomber. Under these conditions, N_2O_4 /fuel mixtures are explosives and are not suitable as rocket propellants.

4.4.1 Dinitrogen Tetroxide/Nitromethane Mixtures

Nitromethane is miscible with N_2O_4 over the entire range of mixture ratios. The eutectic temperature is 217 K (-56°C), and the eutectic mix contains 47 mass-% N_2O_4 . The mixture is detonable.

4.4.2 Dinitrogen Tetroxide/Tetranitromethane Mixtures

The formula of nitromethane is H_3CNO_2 , and one can see that it contains hydrogen (a fuel) and combustible carbon as the central atom. Tetranitromethane (TNM), $\text{C}(\text{NO}_2)_4$, on the other hand, is quite different. The carbon and hydrogen balance in tetranitromethane is more than oxidized, and tetranitromethane can no longer act as a fuel but is an oxidizer. Consequently it can be mixed with other oxidizers such as dinitrogen tetroxide without unduly increasing the shock sensitivity of the mixture. In Germany during World War II, experiments were conducted with a mixture containing 62 mass-% TNM (code name X-Stoff) and 38% NTO (code name U-Stoff). The mixture was designated "XU Stoff." Such mixtures were first studied in Peenemünde in Germany during World War II, and the interest was later revived and more in-depth studies of the physical properties were conducted at the German Deutsche Versuchsanstalt für Luft- und Raumfahrt in Stuttgart-Vaihingen in the mid-1960s.

Both oxidizers, N_2O_4 and TNM by themselves have undesirably high freezing points. When mixing them in the appropriate mixture ratios, one can obtain oxidizer blends with favorably low freezing points and other desirable properties. For instance, the oxygen content in a given volume of N_2O_4 oxidizer can be improved by adding TNM.

Figure 39: Freezing-point diagram of the dinitrogen tetroxide/tetranitromethane system. (Reproduced and modified from [226].)

The freezing point of TNM can be lowered by the addition of 12.6 mass-% N_2O_4 to 271–269 K (–2 to –4 °C), by the addition of more (20 mass-% N_2O_4) down to 265–263 K (–8 to –10 °C), and finally by the addition of 27.5 mass-% N_2O_4 to 253–251 K (–20 to –22 °C) [224, 225]. It appears that these data were obtained not by using pure N_2O_4 but by oxides contaminated with N_2O_3 because the liquid was described as blue. Subsequent melting-diagram determinations used a better grade of N_2O_4 . The tetranitromethane/dinitrogen tetroxide system is completely miscible over the entire range of mixture ratios [226]. The freezing-point diagram in Figure 39 shows a low-melting eutectic containing 65 mass-% TNM and a melting point of 244 K (–29 °C).

Two additional NTO/TNM data points were determined at Rocketdyne in addition to two dinitrogen tetroxide/fluorotrinitromethane (FTM) freezing points listed in Table 35 [35].

The density of $\text{N}_2\text{O}_4/\text{C}(\text{NO}_2)_4$ mixtures increased linearly with the $\text{C}(\text{NO}_2)_4$ content (Figure 40) and can be expressed by the following equation:

$$\rho = 1.4458 + 0.00191 c \text{ C}(\text{NO}_2)_4$$

where ρ is the density in g/cm^3 at 293 K and $c \text{ C}(\text{NO}_2)_4$ is the TNM concentration in mass percent.

Table 35: Melting points of NTO/TNM and NTO/FTM mixtures.

Mixture	Composition, mass-% TNM	Freezing point		
		K	°C	°F
N ₂ O ₄ -TNM	10.0	260.0	-13.1	8.4
N ₂ O ₄ -TNM	20.0	258.3	-14.8	5.4
N ₂ O ₄ -FTM	10.0	259.6	-13.5	7.7
N ₂ O ₄ -FTM	20.0	257.8	-15.3	4.5
For comparison:				
FTM		231.2	-41.9	-43.4

Data source: [35]

Figure 40: Density of dinitrogen tetroxide/tetranitromethane mixtures. (Reproduced and modified from [226].)

Vapor pressure isotherms illustrated in Figure 41 show that the mixture obeys Raoult's law, i.e., it behaves as an ideal mixture and does not form azeotropes or other associations.

The viscosity of N₂O₄/C(NO₂)₄ mixtures exhibits the behavior that is typical for binary mixtures, as illustrated in Figure 42.

Mixtures of NTO with dinitrotoluene that may form as a by-product of making dinitrotoluene for toluene diisocyanate (TDI) manufacturing or making trinitrotoluene (TNT) are highly detonable [227].

Figure 41: Vapor pressure isotherms of the dinitrogen tetroxide/tetranitromethane system. (Reproduced and modified from [226].)

Figure 42: Viscosity of dinitrogen tetroxide/tetranitromethane mixtures at 288.2 K (15.1°C). (Reproduced and modified from [226].)

4.5 Mixtures of Dinitrogen Tetroxide with Fluorine Compounds

One of the many chemicals evaluated as freezing point depressant for N_2O_4 is fluorotrinitromethane $\text{FC}(\text{NO}_2)_3$. The freezing points of these mixtures are listed in Table 35.

5 Chemical Properties of Dinitrogen Tetroxide

5.1 Dinitrogen Tetroxide as a Solvent

Dinitrogen tetroxide is a polar solvent and can dissolve some salts and many organic substances. The ranking of salt solubilities in NTO follows those in non-polar solvents such as diethyl ether. N_2O_4 is often contaminated by materials leached from tank walls, surface-tension PMD screens, and flow control components. Because these salts and their adducts have only limited solubility in N_2O_4 , they precipitate when the saturated solution cools off and cause flow decay problems when small orifices become clogged. The solubility of iron(III) nitrate and other corrosion products in N_2O_4 determines the onset of flow decay.

Among the chemistry in non-aqueous media, reactions in N_2O_4 as a solvent assume a very important role. Dinitrogen tetroxide as a solvent has been thoroughly investigated by Addison in the United Kingdom. A series of publications by Addison [228, 229] summarized the solvent properties of N_2O_4 , but the later publications in this series deal mostly with reactions with sulfur compounds and complex formation with metal salts and are of less interest to rocket propellant chemists. In addition to its use as a solvent, dinitrogen tetroxide and/or nitric acid can also be used as a reactant in numerous reactions with inorganic and organic compounds [230]. Dinitrogen tetroxide is a liquid with unique solvent properties. Because it undergoes autodissociation according to

it is a polar solvent and can dissolve many salts and organic substances. Among the chemistry in nonaqueous media, reactions in N_2O_4 as a solvent assume a very important role [184, 190, 229]. There are also some monographs on non-aqueous solvents that contain sections on dinitrogen tetroxide as a non-aqueous solvent [231].

5.2 Dissociation of Dinitrogen Tetroxide

Dinitrogen tetroxide is the dimer of nitrogen dioxide. The forward dimerization/backward dissociation reactions occur quickly, and the equilibrium concentrations of N_2O_4 are temperature-dependent and pressure-dependent. Dinitrogen tetroxide N_2O_4 vapor is dissociated to the extent of 16.1% into nitrogen dioxide NO_2 at the normal boiling point at atmospheric pressure. From measurements of magnetic susceptibility, it was concluded that the pure liquid N_2O_4 at 273 K contains only 0.7 mass-% NO_2 .

Dinitrogen tetroxide is a hypergolic oxidizer. In order to study the kinetics of hypergolic ignition with N_2O_4 , the extent to which N_2O_4 is dissociated at the time of contact with the fuel needs to be known. This is why this book contains sections on the dissociation of dinitrogen tetroxide. Very rarely is N_2O_4 used as a regenerative coolant in bipropellant rocket engines. If it were, one would have to know whether N_2O_4 dissociates under the conditions in the cooling jacket or not.

Several detailed summaries of the literature on the kinetics and thermodynamics of the dissociation of N_2O_4 have been published and are referenced here for further study [38, 39].

As stated, dinitrogen tetroxide is rarely used as a regenerative coolant, but if it were, it would change its heat transfer properties while heating up in the cooling jacket before being injected into the rocket engine. This change in properties is due to both chemical changes and changes in temperature-dependent physical properties of the constituents of the mixture. Similar changes take place in a N_2O_4 droplet that is injected into a combustion chamber; it heats up and evaporates before it starts to react with the fuel. Another application of N_2O_4 dissociation is in heat pipes, where the heat transport is much more efficient than with a non-dissociating working fluid. N_2O_4 dissociates at the hot end, flows through the gas passage as gaseous NO_2 , recombines at the cold end, condenses to form liquid N_2O_4 , and wicks through the wick by capillary forces to complete the loop. Dissociating N_2O_4 has also been proposed as a working fluid for turbines in which the heat source is a nuclear reactor. This is another reason we are taking a closer look at the dissociation chemistry of N_2O_4 in this chapter. Because there is a change in the number of mols, the equilibrium is not only temperature dependent but also pressure dependent. The dissociation of one molecule of N_2O_4 into two molecules of NO_2 is due to a homolytic bond fission reaction. Homolytic fission is the chemical bond dissociation of a neutral molecule generating two free radicals. The most efficient method of studying N_2O_4 dissociation kinetics and equilibria is by measuring the absorption spectra, which can also be done by remote sensing methods in the atmosphere. Several papers dealing with these analytic methods were referenced in the previous spectroscopic section.

Thermodynamic and transport properties, including enthalpy, entropy, heat capacity, average molecular mass, viscosity, and thermal conductivity, have been calculated for the $\text{N}_2\text{O}_4 \rightleftharpoons 2\text{NO}_2$ equilibrium and also for the $\text{N}_2\text{O}_4 \rightleftharpoons 2\text{NO}_2 \rightleftharpoons 2\text{NO} + \text{O}_2$ equi-

librium from 3000 to 1280 K and from 0.01 to 100 atm [232]. An expression for the thermal conductivity due to chemical reaction was also included.

Dinitrogen tetroxide can dissociate as a homolytic reaction into electrically neutral fragments

or it can convert to the ionic form of nitrosyl nitrate, which then dissociates in a heterolytic reaction into nitrosonium and nitrate ions [233]:

A less likely path of dissociation would theoretically go to nitronium and nitrite ions:

Autodissociation via the heterolytic reaction can be measured by electrical redox potential measurements.

The reversible redox potential of the $\text{NO}_2^+/\text{NO}_2$ couple in liquid N_2O_4 was measured by cyclic voltammetric (CV) examination of the reduction of the nitronium ion as well as the microscopic reverse oxidation of NO_2 [234]. The facile association of NO_2 and dissociation of N_2O_4 were specifically included in the electrode kinetics by a successful computer simulation of the cyclic voltammograms at relatively slow and fast CV scan rates. The kinetics of the N_2O_4 dissociation (k_1) and NO_2 association (k_2) were determined with the aid of single-step chronoamperometry by developing the theoretical working curves based on the CE(mono) mechanism. The strong dependence of the redox potential on the medium is associated with significant NO_2^+ coordination in the solvent. The heterogeneous rate constant (k_s) for electron transfer to NO_2^+ was found to be faster than k_s for NO^+ despite a significantly enhanced value of the intrinsic reorganization energy of NO_2^+ compared to NO^+ for outer-sphere electron transfer.

5.2.1 Experimental Study of Dinitrogen Tetroxide Dissociation

At 263 K (−10 °C), N_2O_4 is a colorless liquid that, upon heating, becomes reddish-brown because of the beginning dissociation leading to nitrogen dioxide [52]

It begins to boil at 294.2 K (21.1 °C). The enthalpy of dissociation in the gas phase at 298 K is 57.3 kJ/mol (13.693 kcal/mol). In the vicinity of the boiling point, the vapor still consists mostly of undissociated N_2O_4 (Figure 43).

The velocity of sound in dinitrogen tetroxide vapor was measured between 274 K (1 °C) and 303 K (30 °C), at pressures between 17 kPa (130 mm Hg) and 101 kPa (760 mm Hg) with sound waves between 9 and 93 kHz [53]. The change of the velocity

of sound with frequency allowed an estimate of the rate of dissociation of dinitrogen tetroxide into nitrogen dioxide, driven by sound energy and the oscillation of local pressure.

It has been attempted to measure the rate of dissociation of N_2O_4 vapor by measuring the attenuation of sound waves as a function of frequency. At sufficiently high frequencies, the velocity of sound is independent of frequency because the N_2O_4 dissociation equilibrium cannot adjust itself fast enough to the local pressure fluctuations as the sound wave moves through [54]. At low frequencies, the intensity and travel velocity of the sound wave are diminished because part of the energy goes toward dissociating N_2O_4 .

Dissociation kinetics can be measured by subjecting N_2O_4 vapor to a shock wave, causing it to be heated very rapidly [235, 236]. As soon as the shock front has passed through the sample, the spectroscopic instrument and photomultiplier record the changing light transmission as it approaches equilibrium at the new temperature and pressure. The rate of dissociation of N_2O_4 in the presence of a large excess of N_2 or CO_2 at pressures from 50 to 707 kPa has been measured by this method. Near 101 kPa, the rate law was

$$-\frac{d[\text{N}_2\text{O}_4]}{dt} = k[\text{N}_2\text{O}_4][\text{N}_2]$$

and the reaction constant was

$$k = 2.0 \times 10^{14} \exp(-11000/RT)$$

See also [237, 238].

Most of the N_2O_4 dissociation studies were done for the vapor phase, and only a few studies were done for the dissociation in the liquid phase. The liquid-phase equilibrium constants for the reaction $\text{N}_2\text{O}_4 \rightleftharpoons 2\text{NO}_2$ in pure dinitrogen tetroxide were measured over the normal liquid range of the substance [194]. The NO_2 concentration in the liquid was determined by comparing its light absorption in the liquid with the absorption of a known concentration in the vapor. The results gave a linear relation between the logarithm of the equilibrium constant and the reciprocal absolute temperature. From the slope of the curve, an average heat of dissociation of N_2O_4 in the liquid phase of 81.6 kJ/mol (19.5 kcal/mol) was derived. The optical measurements of the dissociation equilibrium constant were later confirmed by magnetic susceptibility measurements [193].

Dissociation of N_2O_4 is much less in the liquid state than in the vapor state. In the liquid state, the equilibrium mixture of N_2O_4 and NO_2 can be considered as a solution of NO_2 in N_2O_4 , and the Henry's law coefficient can be derived from vapor pressure measurements of the mixture. Combining vapor pressure measurements with spectroscopic measurements, it is possible to calculate standard enthalpy, free energy, and entropy of the N_2O_4 dissociation in the liquid phase [32].

Rapid pressure and temperature changes such as those experienced by a gas mixture in a supersonic nozzle flow take place faster than the equilibrium of N_2O_4 dissociation can adjust to, resulting in non-equilibrium conditions [239–241]. The viscosity of dinitrogen tetroxide vapor expanding to supersonic velocities in a Laval nozzle will depend on the rate at which the $\text{N}_2\text{O}_4 \rightleftharpoons \text{NO}_2$ equilibrium can adjust to the rapidly changing pressure and temperature environment as it expands.

The equilibrium constant of the dissociation of dinitrogen tetroxide and the kinetic rate of how fast equilibrium is achieved can be measured by a variety of analytical methods, including spectrophotometry, EPR measurements, velocity-of-sound measurements, and electrical conductivity measurements [199].

An all-glass apparatus has been used to measure the thermal conductivity of the system $\text{N}_2\text{O}_4 \rightleftharpoons 2\text{NO}_2$ by a thick-wire variant of the hot-wire method in a temperature range of 305–363 K (32–90 °C) and up to a pressure of about 67 kPa (500 mm Hg) [75]. A correlation between equilibrium constant and the thermal conductivity experimental data was discussed in light of theories based on the assumption of local chemical equilibrium. The discrepancy between the experimental and the calculated values of the heat conductivity, which is particularly large at the lower pressures, showed the necessity of applying non-equilibrium heat transfer theory to interpret the data. Table 36 gives the measured thermal conductivity and equilibrium constants for temperatures from 305 to 363 K (32–90 °C) and pressures from 13 to 70 kPa (100–520 mm Hg). The measured equilibrium constant (in column 5 of Table 36) agreed well with literature data from Giaque and Kemp [21] (in column 6 of Table 36). It may be seen from Table 36 that at any particular temperature, K_p is not strictly independent of pressure. At least a part of this variation of K_p with pressure must be ascribed to gas imperfections. To test this, the equilibrium constant K_p was calculated from fugacities.

The gas-phase equilibrium constants for the dissociation of nitrogen tetroxide, $\text{N}_2\text{O}_4 \rightleftharpoons 2\text{NO}_2$, have been calculated from experimental data based on IR absorption techniques [242]. The quantitative analysis of NO_2 in the mixture was made at varying pressures and temperatures by observation of the 3.425- μm nitrogen dioxide absorption band to obtain equilibrium constants in the temperature range of 300–370 K. It was also shown that the 3.21- μm band previously assigned to NO_2 should be assigned to N_2O_4 .

NO_2 in the atmosphere can be measured by its absorption in the UV/visible range. Its absorption in the long UV range overlaps with that of its dimer, N_2O_4 . To compensate for the interfering contribution of N_2O_4 from studies of NO_2 profiles in the atmosphere, either the form of the temperature dependence of the equilibrium constant for the equilibrium of N_2O_4 and NO_2 in the gaseous state, $K_p(T)$, must be known, or K_p must be measured at the specific temperature of interest.

At 101 kPa (1 atm) and 294 K (70 °F), the fraction α of N_2O_4 vapor dissociated is 0.163, while at the same pressure and 394 K (250 °F), α is 0.954. Thus, a wide range of dissociation levels can be obtained at conditions easily established in the laboratory. The degree of dissociation is summarized in Table 37. Compare this also to Figure 43.

408	135	1

The enthalpy of dissociation in the gas phase at 298K is 57.3kJ/mol (13.693kcal/mol). In the vicinity of the boiling point, the vapor still consists mostly of undissociated N_2O_4 (Figure 43).

Figure 43: Dissociation of dinitrogen tetroxide as a function of temperature and pressure. (Reprinted and modified from [130] with permission from © 1962 American Chemical Society.)

The equilibrium constant K of N_2O_4 dissociation is related to the dissociation fraction α by the equation

$$K = \frac{P_{\text{NO}_2}^2}{P_{\text{N}_2\text{O}_4}} = \frac{4P\alpha^2}{1 - \alpha^2}$$

In turn, nitrogen dioxide is not thermally stable either, but above 473 K (200 °C) it decomposes reversibly in accordance with

until at 923 K (650 °C) this reaction proceeds to completeness [81, 199]. The decomposition of NO_2 can also be achieved by absorption of UV light (436 nm), a process that is closely related to the formation and dispersal of atmospheric smog. The process is reversible because nitric oxide and oxygen eventually react to restore the NO_2 molecule.

Going one step back to discussing the dissociation of N_2O_4 (not NO_2), the equilibrium constant K_p that gives the mol fraction of thermal N_2O_4 dissociation

$$K_p = \frac{[\text{NO}_2]^2}{[\text{N}_2\text{O}_4]}$$

$$K_p = \frac{P_{\text{NO}_2}^2}{P_{\text{N}_2\text{O}_4}} = \frac{4P\alpha^2}{1-\alpha^2}$$

is a function of temperature and can be calculated from [243]

$$\log K_p = -\frac{2692}{T} + 1.75 \log T + 0.00483T - 7.144 \times 10^{-6}T^2 + 3.062$$

where K_p is the equilibrium constant in mm Hg and T is the temperature in kelvin.

Molecular data of N_2O_4 were derived from natural frequencies of IR-active oscillations and freedom of rotation with assumed data on the electronic levels of N_2O_4 in order to develop a model of the molecule in the ideal gas state and to derive an equilibrium constant for its dissociation [244].

Calculations were made for shifting and frozen equilibrium during expansion [65].

A study of the reactions

and

was carried out in a shock tube [245]. For the first of these two reactions, the rate equation was taken to be

$$d[\text{N}_2\text{O}_4]/dt = -k_{D1}[\text{N}_2\text{O}_4][\text{M}] + k_{R1}[\text{NO}_2]^2[\text{M}]$$

based on previous results. With argon as the inert gas M, with a reactant mol fraction of less than 0.1, the rate constant was found to be

$$k_{D1} = 2.2 \times 10^{14} \exp(-11000/RT) \text{L mol}^{-1} \cdot \text{s}^{-1}.$$

The new application of fully dispersed shock waves was found to produce more accurate results than the conventional use of partly dispersed shock waves. For the second reaction, the rate equation was established as

$$d[\text{NO}_2]/dt = -k_{D2}[\text{NO}_2]^2 - k_{D3}[\text{NO}_2][\text{M}]$$

and with argon as the inert gas, the dissociation rate constants were found to be

$$k_{D2} = 3.0 \times 10^9 \exp(-26900/RT) \text{L mol}^{-1} \cdot \text{s}^{-1}$$

and

$$k_{D3} = 3.6 \times 10^{13} \exp(-65400/RT) \text{L mol}^{-1} \cdot \text{s}^{-1}.$$

An analytical description of the flow fields agreed well with the experimental values, which were determined by a light-absorption technique.

The equilibrium constant for the reaction $2\text{NO}_2 \rightleftharpoons \text{N}_2\text{O}_4$ was determined by FTIR spectroscopy of the ν_2 band of NO_2 near $13.3\mu\text{m}$ [246]. Spectra were recorded alternately through two absorption cells of different path lengths. Working within the validity of the Beer-Lambert law of absorption of radiation, an equation was derived that related the equilibrium constant to pairs of gas pressures that gave the same spectral absorbance of NO_2 in the two unequal cells. No knowledge of the absorption coefficient was needed using this technique. All samples were pressurized to 740 mm Hg with high-purity nitrogen, and measurements were taken at room temperature (296 K). Using this two-cell technique, the equilibrium constant was $K_{\text{eq}} = 0.14 \pm 0.02 \text{ atm}$ at room temperature.

The rate of recombination of shocked and dissociated dinitrogen tetroxide can be measured in the reflected shock wave in a shock tube filled with diluted dinitrogen tetroxide [247]. It was shown that the kinetics has a significant influence on the characteristics of a shock wave and a contact discontinuity, such as a wall, from which the shock wave is reflected.

In a nuclear reactor heat exchanger, the dissociating gas does not behave as an ideal gas, and its properties change with time and location as it passes through a heat exchanger [248]. Relaxation times measured from sudden adiabatic compressions at 0.27 to 1 atm were of the order of 0.7–0.14 μs .

The rate of association of NO_2 to N_2O_4 in very high N_2 dilution was measured at pressures from 1 to 207 bar [249]. The relaxation of $\text{NO}_2/\text{N}_2\text{O}_4$ mixtures was followed after laser flash photolysis of N_2O_4 at 248 nm. The high-pressure and low-pressure rate constants at 298 K were as follows:

$$k_{\text{assoc}} = (8.3 \pm 1.0) \times 10^{-13} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1} \text{ (at high pressure)}$$

and

$$k_{\text{assoc}} = (1.4 \pm 0.2) \times 10^{-33} [\text{N}_2] \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1} \text{ (at low pressure)}$$

In the hydrodynamic calculation of transonic flow of dinitrogen-tetroxide in flow channels, one should avoid the use of the hydrodynamic-drag coefficient, which is a sharply varying quantity [250]. Instead, a more accurate method can be based on the hypothesis of a linear approximation of entropy along the axis of the flow.

The equilibrium between N_2O_4 and NO_2 not only affects its use as a rocket propellant but also affects processes in the polluted atmosphere and the potential deposition of N_2O_4 and NO_2 on the surface of ice crystals and water droplets in the upper atmosphere, particularly in cold regions [251]. Similarly, it would also affect the absorption of NO_x fumes vented from a propellant tank in a water-spray absorption tower.

Measurements of stratospheric NO_2 by ground-based visible spectrometers rely on laboratory measurements of absorption cross-sections. When reviewing low-

temperature laboratory measurements, some investigators claimed that literature data disagreed by significant amounts. A recalculation of errors showed that, in general, these disagreements were not all that significant and that errors in the ratios of cross-sections at low to room temperature were between $\pm 3\%$ and $\pm 8.8\%$ [251]. Of these errors, up to $\pm 3.5\%$ were contributed by errors in the equilibrium constant, K_p , in those measurements where the pressure was above 0.1 mbar. The optimum experiment might therefore simultaneously measure the visible and IR spectra.

The velocity of sound in gaseous $N_2O_4 \rightleftharpoons 2NO_2$ was determined at various temperatures [56]. The velocity-of-sound data obtained were used to calculate the mol fractions of N_2O_4 and NO_2 in the $N_2O_4 \rightleftharpoons 2NO_2$ mixtures. From these data, the equilibrium constants of dimerization were calculated for the system at various temperatures and compared to the literature. That work contains a table summarizing and comparing equilibrium constants measured by six previous investigators using four different methods.

The equilibrium constant of the N_2O_4 dissociation was determined at 283 K and at pressures at and below 1 mm Hg using cavity ring-down spectroscopy (CRDS) [252]. CRDS is a sensitive absorption technique that in this case consisted of a 0.5-m long thermostatted stainless steel tube (diameter 0.75 in) sealed by highly reflective mirrors. A flash of 80 mJ of 532-nm light was injected into a dye laser to provide 694-nm light for the experiment. This light was propagated through several apertures before being gently focused into the CRDS cavity. The light exiting at the opposite end of the cavity was gently focused onto and detected by a photomultiplier tube. The output of the photomultiplier was collected on a digital oscilloscope and then transferred to a computer. N_2O_4 is expected to be relatively transparent at 694 nm. The equilibrium constant of 21 ± 5 mm Hg derived from these measurements was below previously used numbers for this constant. Table 38 gives the proposed constants for the standard form of T -dependence of $K_p(T)$ and the predicted values of K_p (283 K) for the dissociation of dinitrogen tetroxide according to the equation

$$K_p(T) = Ae^{-\left(\frac{B}{T}\right)}$$

and the predicted values of K_p at 283 K.

Quantitative measurements of the dimerization of nitrogen dioxide in a gas mixture of NO_2 and N_2O_4 have been made using long-duration pulses from 7.84 and 7.46 μm quantum cascade lasers in an intra-pulse quantum cascade laser spectrometer [255].

5.2.2 Computational Chemistry Treatment of Dinitrogen Tetroxide Dissociation

Molecular dynamics simulations were performed for the thermal dissociation and association reactions $\text{N}_2\text{O}_4 \rightleftharpoons 2\text{NO}_2$ in the gas phase and in liquid N_2O_4 [256]. Energy transfer between intra-fragment vibrational modes and the inter-fragment translational mode, which occurs at the inner turning point of the inter-fragment potential, was found to be the dominant prompter of the dissociation and association reactions.

Reacting systems containing N_2O_4 and NO_2 in equilibrium, pure or dissolved in organic solvents, were modeled in two ways: **(1)** assuming that all species in the system are hard spheres with an attractive mean field component (HSA), and **(2)** using a semi-empirical EOS [257]. In both cases, estimates of the relative size of the species, obtained by Monte Carlo simulations, were made to reduce the number of adjustable parameters. As a result, for a pure system, both the HSA model and the semi-empirical EOS required only three adjustable parameters. The agreement between both model predictions and experimental results was good, with higher accuracy for the semi-empirical EOS. The predicted effect of pressure on the equilibrium constant of the gas mixture was underestimated by both models. The predicted dissociation constants of N_2O_4 in the liquid phase were underestimated by about 25% by the HSA model and overestimated by 5% by the semi-empirical EOS.

Classical molecular dynamics simulations of liquid NO_2 and $\text{N}_2\text{O}_4 \rightleftharpoons \text{NO}_2$ and *ab initio* molecular orbital calculations were carried out to elucidate the $\text{NO}_2 \cdots \text{NO}_2$ attraction potential, and an orientation-sensitive pairwise potential (OSPP), which can reproduce highly anisotropic character of covalent bonding between N—N, was formulated [258]. The reactive liquid N_2O_4 was modeled as liquid NO_2 , which interacts with the OSPP potential between N—N atoms and Lennard-Jones potentials between N—O and O—O atoms. The likelihood of more than two NO_2 molecules associating to a trimer or tetramer is extremely small. The equilibrium constant for the dissociation reaction was derived by computing the potential of mean force as a function of the N—N distance reaction coordinate. The OSPP potential reproduced the observed liquid-phase equilibrium properties fairly well.

The $\text{N}_2\text{O}_4 \rightleftharpoons 2\text{NO}_2$ dissociation reaction was investigated at a high level of theory using the couple cluster with all single and double excitations and connected triples and complete active-space self-consistent field approaches [259]. Including an estimate for basis set superposition error, ΔH^{298}_0 for the dissociation reaction was predicted to be 53.4 kJ/mol (12.76 kcal/mol). (For comparison, experiments by others measured 54.8–57.3 kJ/mol [13.1–13.7 kcal/mol].)

Transition state dynamics of dissociation and association reactions $\text{N}_2\text{O}_4 \rightleftharpoons 2\text{NO}_2$ in the liquid state were studied by classical molecular dynamics simulations of reactive liquid NO_2 at 298 K [260]. One possible path of dissociation is the dissociation via bond transfer from a dimer to a monomer NO_2 through the transition state of a $(\text{NO}_2)_3$ trimer. The reactant experiences the transition state of a $(\text{NO}_2)_3$ trimer for a “long” time (1–10 ps) in NO_2 -mediated bond transfer reactions.

5.3 Isomerization of Dinitrogen Tetroxide

Under certain conditions, dinitrogen tetroxide can react not in its symmetric form of O_2NNO_2 but also in the form of its isomer nitrosyl nitrate NO^+NO_3^- . The kinetics of the reaction of dinitrogen tetroxide/nitrogen dioxide with hydrazoic acid in the gas phase were examined between 293 and 323 K [261]. The reaction proceeded as a reaction of second order with respect to NO_2 and first order with respect to HN_3 . The negative temperature coefficient of the reaction rate indicated an exothermic pre-dissociation equilibrium. The stoichiometry of the reaction and the abnormal Arrhenius factor indicated that N_2O_4 does not react as symmetric O_2NNO_2 but rather in the form of its isomer nitrosyl nitrate NO^+NO_3^- . This may also be the reactive species in hypergolic reactions of N_2O_4 with amines and hydrazines.

5.4 Photolysis of Dinitrogen Tetroxide

Unwanted photolysis of N_2O_4 takes place in a UV-visible spectrophotometer that is used to measure the concentration of NO_2 . Photolysis of N_2O_4 and NO_2 takes place in the upper atmosphere as a key step in the formation and decay of smog. Photolysis of N_2O_4 in the presence of oxygen or ozone was attempted as a method to synthesize higher oxides of nitrogen.

A molecular beam of N_2O_4 molecules was photodissociated by an excimer laser at 193 and 248 nm [262]. The time-of-flight distribution of NO_2 photofragments was consistent with the formation of two electronically excited NO_2^* molecules in the $\bar{\text{A}}(^2\text{B}_2)$ or $\bar{\text{B}}(^2\text{B}_1)$ state. Visible emission from NO_2^* was observed in the photolysis at both 193 and 248 nm excitation. The parallel angular distribution of the NO_2 photofragments showed that at 193 nm N_2O_4 has a transition dipole along the N–N axis, and the dissociative lifetime was estimated to be less than 1 ps.

Velocity and angular distribution of the products of N_2O_4 photodissociated at 193 nm showed evidence for only N–N bond fission, with no significant branching to N–O bond fission or NO elimination products [263]. The translational energy distribution of the N–N bond fission products was bimodal, indicating that at least

two different $\text{NO}_2 + \text{NO}_2$ product channels contributed significantly to the observed products. Both product channels had an anisotropy parameter of $\beta = 1.7 \pm 0.2$.

Nitrogen dioxide was photolyzed at room temperature in a long-path infrared cell [264]. The concentrations of NO_2 and N_2O_5 were followed as a function of time, and the molecular modulation spectrum of nitrogen dioxide was obtained in a steady-flow experiment with 1 atm of nitrogen. The rate constant ratios and standard deviations were as follows:

$$\begin{aligned}k_1 \frac{[\text{M}]}{k_2} &= 0.18 \pm 0.01 \\k_3 \frac{[\text{M}]}{k_2} &= 0.22 \pm 0.01 \\ \frac{k_4}{K} &= 0.71 \pm 0.05 \text{ s}^{-1}\end{aligned}$$

where

- (1) $\text{NO} + \text{O} + \text{M} \rightarrow \text{NO}_2 + \text{M}$
- (2) $\text{NO}_2 + \text{O} \rightarrow \text{NO} + \text{O}_2$
- (3) $\text{NO}_2 + \text{O} + \text{M} \rightarrow \text{NO}_3 + \text{M}$
- (4) $\text{NO}_3 + \text{NO} \rightarrow 2\text{NO}_2$

$$K = ([\text{N}_2\text{O}_5]/[\text{NO}_2][\text{NO}_3])_{\text{eq.}}$$

By using literature values for k_1 ($6.9 \times 10^{-32} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$) and for K ($1.24 \times 10^{-11} \text{ cm}^{-3}$), the values of the elementary rate constants were

$$\begin{aligned}k_2 &= 9.2 \times 10^{-12} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1} \\k_3 &= 8.2 \times 10^{-32} \text{ cm}^6 \text{ mol}^{-2} \text{ s}^{-1} \\k_4 &= 8.7 \times 10^{-12} \text{ cm}^3 \text{ mol}^{-2} \text{ s}^{-1}\end{aligned}$$

Multi-reference configuration interaction calculations were performed for vertical excitation energies and potential curves of N_2O_4 in D_{2h} symmetry [265]. The strong absorption of N_2O_4 around 185 nm was assigned to the transition from the ground state to $1^1B_{1u}(\sigma\text{O} \rightarrow \sigma^*\text{N}-\text{N})$ rather than $1^1B_{2u}(\pi\text{O} \rightarrow \pi^*\text{NO}_2, n \rightarrow \sigma^*\text{N}-\text{N})$, as previously assumed. N_2O_4 is placed in the yz -plane, with $\text{N}-\text{N}$ axis along z . The weak absorption around 340 nm was assigned to $11B_{3u}$. Excitation to 1^1B_{2u} was calculated at 227 nm. Multi-reference configuration interaction (MRCI) singlet and triplet potential curves for the dissociation $\text{N}_2\text{O}_4 \rightarrow 2\text{NO}_2$, combined with a table of NO_2 states correlating with those of N_2O_4 , indicated possible products of photodissociation at various wavelengths. The extensive literature on the photodissociation of N_2O_4 was reviewed and updated. Density functional theory geometry optimizations were performed on low-lying singlet and triplet states.

5.5 Radiolysis of Dinitrogen Tetroxide

The radiolysis of dinitrogen tetroxide has been studied because N_2O_4 may decompose under the influence of cosmic radiation during long-duration space missions. Solar cosmic rays have a high-energy proton component. Satellites in the van Allen belt around Earth and in the radiation belt around Jupiter are subjected to intense radiation that may cause propellants to decompose. On long-term deep-space missions, radioisotope thermal generators (RTGs) provide electric power from the heat generated by the decomposition of radioactive isotopes. Although RTGs are shielded and placed on extendable booms away from the spacecraft core, some radiation penetrates the shielding. Propellant tanks in vicinity to RTGs are still subjected to nuclear radiation. Because oxidizers are less sensitive to radiation damage than fuels, it would be best to design the spacecraft such that the oxidizer tank is between the radiation source and the fuel tank. Both the United States and the former USSR have flown satellites with nuclear fission reactors such as SNAP-8 as powerplants. Some of these satellites may have used NTO/MMH thrusters for attitude control, orbit adjustment and controlled de-orbit.

Radiolysis of N_2O_4 opens up new paths of chemistry, and another reason radiolysis has been studied is to look for the formation of higher, more energetic oxides of nitrogen that may also be useful as rocket propellants (if they are stable enough to be stored).

The ^{60}Co γ -radiolysis of liquid dinitrogen tetroxide $\text{N}_2\text{O}_4(\text{L})$ as a function of temperature, gas-to-liquid volume ratio, dose rates, and method of $\text{N}_2\text{O}_4(\text{L})$ purification showed that the radiolytic products were N_2 , N_2O , and N_2O_5 [266–268]. The material balance of the O_2 released at post-irradiation thermal equilibrium as compared with the calculated O_2 derived from the production of N_2 and N_2O from N_2O_4 was accurate to within 10%. $\text{N}_2\text{O}_4(\text{L})$ was relatively radiation resistant, having a G value of only 0.075, the ratio of N_2 and N_2O product formation being 2:1. The addition of O_2 , over the partial pressure range of 26.7–46.7 kPa (200–350 mm Hg), resulted in an elevated G value for N_2O_5 formation.

Radiolysis experiments with liquid dinitrogen tetroxide (inhibited and uninhibited) were conducted in stainless steel vessels of approximately 15 mL under γ -irradiations by ^{60}Co at a dose rate of 5.76×10^5 rad/h and a temperature of 294 K (21°C) [269]. Sample vessels were evacuated prior to being filled with N_2O_4 . After filling, the liquid N_2O_4 was frozen, and any non-condensable gases were removed by pumping. Non-condensable gases at liquid N_2 temperature formed by decomposition of N_2O_4 were determined as a function of time and radiation dose by PVT relationships. The results of experiments at the dose rate of 5.76×10^5 rad/h for both the uninhibited and inhibited forms of N_2O_4 were displayed as mols of non-condensable gas formed per gram of liquid N_2O_4 as a function of radiation dose. The decomposition rate at a fixed dose rate appeared to be a function of the extent to which the sample vessel was filled, which suggested that the vapor is more

susceptible than the liquid to decomposition and that there is some interaction with the walls of the vessel. The major non-N₂O₄ component of the gas space was nitric oxide, NO, and its rate of formation appeared to be about the same in both cases at the dose rate used, 5.76×10^5 rad/h. For the uninhibited N₂O₄, the *G* value of $G(\text{N}_2) = 6.1 \times 10^{-2}$ molecules/100 eV which was similar to the results reported by Castorina of 5.2×10^{-2} . The only other product found in addition to NO and N₂ was nitrous oxide, N₂O, which was formed at a rate slightly greater than that of nitrogen in the case of the uninhibited nitrogen tetroxide and slightly less in the case of the inhibited form.

The liquid-phase radiolysis of NO solutions in N₂O₄ at nitrogen monoxide concentrations up to 15 mass-% was studied at 303–413 K (30–140 °C) and pressures of 1.2–6.0 MPa [270]. The radiation-chemical yield of decomposition of liquid N₂O₄ was found to be 1.5–2.0 orders of magnitude lower than that of gaseous N₂O₄. The dissolution of nitrogen monoxide (to 15 mass-%) in N₂O₄ increased the radiation-chemical yields of nitrogen and dinitrogen oxide from 0.03 ± 0.002 to 0.15 ± 0.002 and from 0.005 ± 0.0005 to 0.03 ± 0.001 , respectively.

It is thus unlikely that cosmic radiation affects the propellant properties of NTO during long space missions. Fuels such as N₂H₄ or MMH would suffer from radiolysis much worse than NTO would.

5.6 Reactions of Dinitrogen Tetroxide with Inorganic Compounds

Dry dinitrogen tetroxide reacts with many inorganic compounds, but its reactivity is greatly enhanced in the presence of traces of moisture. The main concern about reactions of liquid N₂O₄ with inorganic materials is about the corrosion of metal tanks during storage and flight use of N₂O₄, resulting in leached metals being dissolved as metal salts or precipitated as sludge causing flow decay problems.

Metal nitrate/N₂O₄ adducts of the type $\text{M}(\text{NO}_3)_x \cdot y\text{N}_2\text{O}_4$, in which N₂O₄ molecules are trapped in the metal nitrate lattice, were synthesized from the reaction of N₂O₄ and the corresponding metal salts [230]. Since liquid N₂O₄ evaporates at 294.3 K (21.15 °C) under atmospheric pressure, $\text{M}(\text{NO}_3)_x \cdot y\text{N}_2\text{O}_4$ adducts are a very convenient and thermally stable source of N₂O₄. The iron salt with a composition of $[\text{NO}]^+ [\text{Fe}(\text{NO}_3)_4]^-$ is the main culprit in flow decay in NTO, which has become saturated with this sparsely soluble compound and which precipitates if the NTO solvent is cooled. Upon contact with moisture, it is readily hydrolyzed to hydrated iron(III) nitrate. It can be sublimed under vacuum, but it decomposes to a similar compound $[\text{NO}_2]^+ [\text{Fe}(\text{NO}_3)_4]^-$ [271].

A five-phase program has been conducted to define and determine elimination techniques for flow decay, a troublesome phenomenon [272, 273]. Flow decay has been shown to arise from the deposition of N₂O₄-soluble iron compounds in valve orifices. This deposition impedes the flow of propellant and, in extreme cases, clogs the valve completely. The five phases of the program involved compound formation, compound identification, compound solubility, compound elimination,

and efficiency evaluation of removal techniques. The solubility of $\text{Fe}(\text{NO}_3)_3 \cdot \text{N}_2\text{O}_4$ in pure N_2O_4 over the temperature range of 273–311 K (0–37.8 °C/32–100 °F) is quite low, on the order of 0.1–2 ppm (in terms of Fe concentration), with a slight positive temperature coefficient of solubility. Water at the military specification limit (0.1 mass-%) and NO up to 1 mass-% had no effect on solubility. Higher water concentrations increased the solubility. The addition of acetonitrile, perfluoroacetonitrile, benzonitrile, perfluorobenzonitrile, ethyl acetate, or perfluoroacetone was tested in the hope that these compounds would prevent precipitation of $[\text{NO}]^+ [\text{Fe}(\text{NO}_3)_4]^-$. Acetonitrile added to N_2O_4 dissolved the deposit. The addition of 0.25 mass-% acetonitrile to N_2O_4 prevented the formation of deposits in a flow system. It was attempted to identify the compound in N_2O_4 by NMR or EPR, but the sensitivity of these methods in the presence of excessive $\text{NO}_2/\text{N}_2\text{O}_4$ was insufficient. A Mössbauer spectrum was taken of the anhydrous synthetic $\text{Fe}(\text{NO}_3)_3 \cdot \text{N}_2\text{O}_4$ to characterize this material more fully and to determine whether this technique would be useful in determining the structure of the actual flow-decay material. The isomer shift observed was ~ 0.25 mm/s. The broad line width was probably caused by a fairly long spin-spin relaxation time. The absence of a sizable quadrupole splitting suggested that the iron site (or sites) had essentially undistorted octahedral or tetrahedral symmetry. The spectrum observed for $\text{Fe}(\text{NO}_3)_3 \cdot \text{N}_2\text{O}_4$ was quite different from that of $\text{Fe}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$, which has a shift ~ 0.1 mm/s less than the $\text{Fe}(\text{NO}_3)_3 \cdot \text{N}_2\text{O}_4$ and has a line width approximately twice as broad. The spectrum did not resemble spectra of the simple iron oxides.

The crystal structure of the adduct $\text{Fe}(\text{NO}_3)_3 \cdot 1.5\text{N}_2\text{O}_4$ indicated that it should be represented as $3\text{NO}^+ \text{NO}_3^- \cdot 2[\text{Fe}(\text{NO}_3)_4]^-$ [274]. Vibrational spectroscopy provided evidence for interaction between the NO_3^- and 3NO^+ ions, and the properties could be correlated in terms of a weakly bonded $[\text{N}_4\text{O}_6]^{2+}$ group that may also be present in solutions of N_2O_4 or the adduct in pure nitric acid.

5.6.1 Solubility of Iron Nitrate in Dinitrogen Tetroxide

The limited solubility of iron nitrate and its adducts in dinitrogen tetroxide is the cause for precipitation of solids or gels and flow decay. Several experimental studies were conducted to determine the solubility limit of iron nitrate in NTO and MON with different water and NO contents.

If the initial propellant composition is varied (within the limits of NAS 3620), the iron solubility changes. The most distinct change is the increase of iron solubility with NO content. If the composition is held constant and the temperature is increased, the solubility increases with an increase in temperature. In selecting the optimum operating temperature for a satellite propellant tank, increasing the temperature widens the soluble range, but it also accelerates the rate of corrosion. Researchers at NASA's WSTF conducted a series of tests to measure the solubility of the material that causes flow decay in MON-1 and MON-3 [11, 275–277]. The solubility was measured as a function of NO concentration, water equivalent concentration, and temperature. The

results indicated that the solubility is very dependent on NO content and to a lesser degree is affected by the water content. In a second series of tests, flow decay was deliberately induced when flowing MON through windowed orifices and a Space Shuttle RCS engine. The tests showed that the oxidizer needs to be supersaturated with iron nitrate to produce the flow decay phenomenon. Figure 44 shows the solubility of iron nitrate in MON as a function of temperature, with the NO content as a secondary variable but with constant water content (0.1% H₂O equivalent). Similar charts exist for water equivalent contents of 0.05% H₂O, 0.15% H₂O, and 0.20% H₂O, but they do not differ very much. The data from 350 data points were curve fitted and resulted

Figure 44: Solubility of iron nitrate in MON as a function of temperature and NO content. (Reproduced and modified from [11].)

in an equation that expresses the saturation concentration of iron nitrate in N_2O_4 as a function of temperature, NO content, and H_2O content:

log iron concentration (in parts per million)

$$\begin{aligned}
 = & -2.355 + 0.0929T - 0.00108T^2 + 4.153 \times 10^{-6}T^3 \\
 & + [-0.935 - 0.137T + 0.00305T^2 - 1.450 \times 10^{-5}T^3] \text{ water equivalent percent} \\
 & + [0.0311 + 0.000462T + 0.0000189T^2 - 1.417 \times 10^{-7}T^3] \text{ NO percent}
 \end{aligned}$$

where T is the temperature in kelvin.

When replotting the WSTF data in a format that shows the iron solubility as a function of water content with temperature as the secondary variable, it was noted that the slope of the iron solubility curves changed with temperature [278]. As shown in Figure 45, iron solubility increased with water content at high temperatures but decreased with water content at low temperatures.

Figure 45: Iron solubility in MON-1 as a function of water content and temperature. (Reproduced and modified from [278].)

Applying this solubility information to the conditions inside the Galileo Jupiter space probe oxidizer tank containing MON-1 with 0.8% NO and 0.08% H_2O , it was predicted that flow decay problems might have to be expected if the temperature were allowed to drop to less than 263 K (10°C) (Figure 46) [279–281].

Figure 46: Iron solubility limits determine flow decay problems in MON oxidizer tank. (Reproduced and modified from [278].)

When studying the solubility of iron nitrate in MON-1 and MON-3, it was found that solubility is higher in MON-3 than in MON-1 [282]. Solubility increased with water content in the range of 0–0.1 mass-% H_2O equivalent and increased with temperature in the range of 278–308 K (5–35 °C). Filtration of MON saturated with iron nitrate through filters with pore sizes in the range of 0.2–1 μm showed that the finer membranes removed more iron. That indicates that iron nitrate exists in MON in particle sizes below the submicron level.

The solubilities of metal nitrates in liquid dinitrogen tetroxide containing 0.4–2% HNO_3 additive at 293 K were determined by emission spectrographic and colorimetric methods [283] (Table 39).

Table 39: Solubilities of metal nitrates in liquid dinitrogen tetroxide.

Nitrate Analysis method	Solubility, mass-% Spectrographic	Solubility, mass-% Colorimetric
Al(III)	4.6×10^{-4}	3.8×10^{-4}
Fe(III)	1.8×10^{-4}	4.0×10^{-4}
Ca(II)	3.9×10^{-5}	
Mg(II)	7.0×10^{-5}	
Ni(II)	3.7×10^{-5}	
Cr(III)	5.3×10^{-5}	

Data source: [283]

5.6.2 Reactions of Dinitrogen Tetroxide with Water

The reactions of dinitrogen tetroxide with water are essentially the same as those already discussed in the chapter “Nitrogen Dioxide” for reactions of nitrogen dioxide with water. Dinitrogen tetroxide has been described as the mixed anhydride of nitrous and nitric acids because of its reaction with water that gives a mixture of nitrous acid and nitric acid. When dinitrogen tetroxide is dissolved in a large excess of water in the absence of oxygen, nitrous and nitric acids are formed in equal amounts:

Nitrous acid is a weak acid ($K_a = 6 \times 10^{-4}$ at $303\text{ K} = 30^\circ\text{C}$), so it will not dissociate appreciably in aqueous solution. The un-ionized acid decomposes into nitric acid and nitric oxide, though only slowly at low temperatures, until equilibrium is reached. All the reactions are reversible. In the presence of dilute alkali, the reaction is no longer reversible. This is a key reaction for the removal of NO_2 and N_2O_4 vapors from pressurant gases vented from NTO tanks after a completed rocket test by passing the NO_x -loaded gases through a scrubber with an aqueous solution. This is also an important reaction in the manufacturing of nitric acid. The reaction also takes place between NO_x and moisture in the atmosphere and is part of the abiotic nitrogen fixation cycle.

Liquid dinitrogen tetroxide and water form two liquid phases over a wide range of compositions. The upper layer is largely aqueous nitric acid, and the lower layer is deep blue due to the presence of dinitrogen trioxide. At 273 K , the upper layer contains 47 mass-% N_2O_4 , and the lower layer contains 98 mass-% N_2O_4 . If the mixture is heated to 340 K (67°C), the two phases combine into one phase. In the presence of NO or N_2O_3 , the hydrolysis of N_2O_3 is much faster than the reaction of N_2O_4 with water.

Kinetic evidence has identified N_2O_4 as the chief reactant species in the $\text{NO}_2/\text{N}_2\text{O}_4/\text{H}_2\text{O}/\text{HNO}_3$ system [284, 285]. The equilibrium data for this system with an apparent temperature independence could be more accurately expressed in terms of N_2O_4 instead of NO_2 . The ionization of N_2O_4 in solution is a key step. The ionic nature of the reaction would seem to preclude the existence of a purely gas-phase reaction between these nitrogen oxides and water.

In the absence of oxygen, and with varying amounts of nitrogen to adjust the total pressure in the gas phase, the mixture consisting of N_2 , NO , NO_2 , N_2O_4 , N_2O_3 , HNO_2 , and HNO_3 is impossible to analyze with any given single method. Multiple methods have to be used to characterize the complex equilibria in this reacting mixture [286]. One could start with a known amount of concentrated nitric acid, allow an equilibrium amount of $\text{NO}_2/\text{N}_2\text{O}_4$ to dissolve in the liquid phase, and then analyze for NO and NO_2 in the gas phase. See also [287].

5.6.3 Reactions of Dinitrogen Tetroxide with Ammonia

The slow gas-phase reaction of N_2O_4 with NH_3 under conditions that avoid ignition leads to ammonium nitrate [288]:

Ammonia reacts even with solid N_2O_4 readily and extensively. Because of the secondary exothermic reactions, the N_2O_4 decomposition is complete.

Reactions of ammonia with NO , NO_2 , and NO_x have been investigated very thoroughly as part of the stack gas NO_x removal by injection of ammonia into hot stack gases (with or without the presence of a catalyst) to prevent atmospheric pollution.

5.7 Reactions of Dinitrogen Tetroxide with Organic Compounds

Many organic compounds dissolve in N_2O_4 at room temperature without reaction, e.g., saturated hydrocarbons, aromatic hydrocarbons, halocarbons, nitro-compounds, and carboxylic acids. Substances that react with it include unsaturated hydrocarbons, alcohols, amines, and ketones [39]. Ethers, tertiary amines, and many oxygen-containing and nitrogen-containing heterocyclic compounds form adducts similar to Lewis adducts. Most tertiary amine adducts contain two molecules of the base per each N_2O_4 molecule.

The reaction of N_2O_4 with alcohols parallels that with water and leads to an equilibrium with alkyl nitrites:

In the gas phase, a mist of nitric acid vapor is formed. In solution, two separate liquid layers are formed, one rich in nitric acid and the other rich in nitrite ester [289]. For additional information about reactions of NO_2 and N_2O_4 with organic compounds, we refer readers to other publications in the literature [290]. Other reactions are summarized in conference proceedings about nitration methods [291]. Similar reactions can be achieved by using N_2O_3 instead of N_2O_4 [292].

In nitration reactions, N_2O_4 may react in the form of nitrosonium nitrate NO^+NO_3^- , which can form by oxidation of NO in inert solvents at cryogenic temperatures. Nitrosonium nitrate may be an intermediate in the reaction of N_2O_4 with olefins [293].

In our book, we are mostly interested in the NTO and MON reactions that lead to hypergolic ignition with reactive fuels.

Reactions of N_2O_4 with secondary amines give nitrosamines as intermediate products. In ether solutions at low temperatures, reaction of N_2O_4 with tertiary amines forms molecular addition compounds that can be isolated as precipitates at low temperatures and are unstable at room temperature [294].

Because N_2O_4 reacts with many organic compounds, it has been very difficult to find elastomeric materials for gaskets, O-rings, valve seats, and expulsion bladders for use with N_2O_4 .

5.8 Analysis of Dinitrogen Tetroxide and Its Mixtures

In subdividing a chapter on the analysis of rocket propellants, one can either subdivide by the method used or by the analyte to be analyzed. In this chapter we have chosen to subdivide the following by the analytical method used.

Analytical methods are required for dinitrogen tetroxide and nitrogen dioxide for several tasks, which include ensuring the quality of liquid propellants filled into rockets at the launch pad and monitoring work spaces for safe breathing-air conditions. The methods described here are applicable to the rarely used pure N_2O_4 as well as the more commonly used mixed oxides of nitrogen, which consist of N_2O_4 with varying amounts of N_2O_3 as an additive. One of the more important analytical tasks in handling N_2O_4 and MON oxidizers is the analysis of the NO or N_2O_3 content in MON.

Because the composition of MON samples may change if the sampling of propellant from a large reservoir is not done properly or because contaminants may be introduced if incompatible sampling equipment is used, correct and reproducible analysis results can be obtained only if the sampling is done correctly [295].

NASA Specification KSC-SPEC-P-0018 [296] describes the sampling and analysis method for liquid NTO and MON that has been off-loaded from a spacecraft after a flight and stored in a storage tank. It was assumed to be contaminated and had to be analyzed, dried, NO-content-adjusted, and re-analyzed before it could be recycled for future use. This specification provides a means of categorizing recovered propellants for either reclamation for alternate reuse or for reprocessing to the original manufacturer's specification purity. See also [297].

5.8.1 Contaminants Commonly Found in Dinitrogen Tetroxide

Many contaminants that are potentially harmful to applications in rocket engines can be found in dinitrogen tetroxide that has not been properly manufactured and stored. These contaminants include volatile and non-volatile contaminants. Volatile contaminants are nitric acid, nitrosyl chloride, bromide, water, and nitrous acid.

Less volatile contaminants are sulfuric acid and nitrososulfuric acid. Non-volatile contaminants are typically metal salts of metals that were leached from container walls or flow control components, such as valves and filters.

5.8.1.1 Iron Contamination in Dinitrogen Tetroxide or MON

The most troublesome contaminant in dinitrogen tetroxide is partially hydrolyzed iron(III) nitrate or iron(III) nitrosyl tetranitrate, formed by the interaction of nitric acid with tank walls, surface tension screens, and filter screens. This material can form a gelatinous deposit in flow orifices, causing flow decay. For further investigations into causes of flow decay in N_2O_4 systems, see Section 6.3.

Appendices to a final report on flow decay [273] contain three different methods for the analysis of iron in NTO, including 4,7-diphenyl-1,10-phenanthroline or 1,10-phenanthroline spectrophotometric methods and a flame atomic absorption method.

The contaminants found in N_2O_4 causing flow blockage in ground service equipment at the launch site and collected on filter screens have been analyzed and identified as nitrosyl tetranitratoferrate $[NO]^+[Fe(NO_3)_4]^-$ [298, 299]. The stainless steel filter containing the contaminant was obtained from Vandenberg Air Force Base. Approximately 18000 gallons of N_2O_4 had been passed through this filter, which was located in the transfer line between the oxidizer transport trailers and the ready-storage vessel. An authentic sample of this material was synthesized in the laboratory for comparison purposes. The isolation and identification of this compound in actual NTO or MON propellant samples is difficult because it is very hygroscopic. Upon contact with moisture, it is readily hydrolyzed to hydrated iron(III) nitrate. It can be sublimed under vacuum, but it decomposes to a similar compound $[NO_2]^+[Fe(NO_3)_4]^-$ [271].

Some impurities have a pronounced effect on the corrosivity of N_2O_4 toward metals [300]. The main impurities in dinitrogen tetroxide are iron compounds leached from stainless steel container walls.

A comparison of two recommended methods for iron analysis, the Rocketdyne procedure MRTB 60-519 and the NASA procedure TR-248-001, showed that the Rocketdyne procedure worked well for iron contents above 0.5 mg Fe/kg N_2O_4 , but the NASA procedure, which used a hermetically closed system, could analyze iron content over a wider range of concentrations [301]. Either method would give erroneous results if iron existed in the form of a volatile iron compound (e.g., iron carbonyl or iron nitrosyl). It was shown that under the conditions of the NASA method, there are no volatile iron compounds in the samples. In order to test the suspected volatility of iron compounds, a sample of nitrosyl iron(III) tetranitrate had to be prepared, which would then be used to dope pure, iron-free NTO to generate known iron concentrations in the oxidizer [302]. The chosen method for preparation of nitrosyl iron(III) tetranitrate was the reaction of iron pentacarbonyl with dinitrogen tetroxide. The product contained ~19% Fe, while the theoretical iron content should have been 16.7% Fe.

The iron content in green dinitrogen tetroxide can be determined by flame atomic absorption spectrometry [303]. By optimizing working-condition and sample-handling methods, the detectable concentration of iron is 0.060 mg/L, the recovery is 98.8–101.4%, and the relative standard deviation is less than 2%.

5.8.1.2 Halogen Contamination in Dinitrogen Tetroxide or MON

One of the most troublesome contaminants in NTO is chloride in the form of nitrosyl chloride. The methods for chloride analysis in NTO have been improved by researchers at NASA's WSTF over the years [304, 305].

The military-specification method for chloride analysis in MON does not differentiate between chlorine and bromine and may not detect bromine if it is present in the form of bromate. It appears that bromide in MON becomes oxidized to bromate during hydrolysis with sodium hydroxide solution, and bromate escapes the analysis. A more accurate analysis and separation of chloride, bromide, and bromate is possible if a known amount of potassium iodide is added to the sample to be analyzed. Iodide reduces bromate to bromide. Total alkaline soluble chlorine and bromine containing compounds can be individually quantified using a solution procedure adapted from a WSTF procedure and an inductively coupled plasma-mass spectrometry (ICP-MS) procedure developed at TRW [117]. The TRW-developed ICP-MS method used to quantify these halogens is different from the methods described in the military-specification and the WSTF procedure. The sample is prepared by hydrolyzing 5 g of oxidized MON-3 in 50 mL of 5-N sodium hydroxide. The TRW method differentiates chloride and bromide using mass spectrometry, whereas the WSTF method differentiates these compounds using a potentiometric titration. In both cases, bromine-containing compounds were found to be the major halogen containing compounds present in some MON samples. The military-specification method, which is a simple silver nitrate titration, determines only the combined alkaline soluble chlorine and bromine-containing compounds concentration reported as a single chloride result, and bromate may be missed. The titration method detected 33% less alkaline soluble bromine.

5.8.1.3 Equivalent Water Present as Nitric Acid

Water is a common impurity in NTO or MON oxidizer, but the analytical problem it presents is that it is not present simply as H_2O but reacts with the nitrogen oxides that are present to produce both nitrous and nitric acid. Thus, the analysis of total water content must take into account these acids. The analytical methods commonly used consider the nitric oxide concentration and a measured value for the nitric acid, found by near-IR spectrophotometry. With knowledge of the equilibrium constants for the reactions forming the nitrous and nitric acids, and the disassociation of nitrous acid into nitric oxide and dinitrogen tetroxide, the total "water equivalent" can be calculated.

The analytical results of corresponding water in green dinitrogen tetroxide (MON-1) may be distorted by other effects. It has been suggested to revise the Chinese national military standard for MON-1 to avoid such difficulties [306].

The method for determining equivalent water in NTO or MON by gas chromatography may have a number of shortcomings and is fraught with uncertainties about the form in which the water exists in the oxidizer, most of it being in the form of HNO_3 , which is difficult to run through a gas chromatograph without decomposition and cor-

rosion [307]. In order to determine the uncertainty of the equivalent water content in NTO and MON by gas chromatography, the equivalent water content of NTO was measured by SC-200 gas chromatograph apparatus according to the equivalent water-content chromatography measurement method specified by GJB 1964-1994 and GJB 1673-1993. GJB 1964-1994 and GJB 1673-1993 are analysis methods used at the Xichang Satellite Launch Center in Liangshan, China. The standard uncertainty, combined uncertainty, and expanded uncertainty were analyzed and evaluated, applying the measured data. The combined standard uncertainty was 0.0327%, and the expanded uncertainty was 0.065% (coverage factor $k = 2$).

5.8.2 Assay Methods for Dinitrogen Tetroxide

The procurement and transfer of rocket propellants is controlled by quality-control specifications that are frequently issued by the U.S. Armed Forces or other government agencies, such as NASA. The main document controlling the quality of dinitrogen tetroxide is MIL-P-26539, which has undergone many revisions during the past several decades. Table 41 in Section 5.8.8 summarizes the dates and scope of some of the most recent changes to this specification.

The most undesirable contaminant in N_2O_4 is water, which is readily absorbed from the air if the container is not securely closed; also, water is sometimes inadvertently left behind in freshly washed but poorly dried containers and transfer hoses. Water and N_2O_4 or NO_2 will gradually react, first forming nitrous acid and nitric acid and later, in the presence of air, forming more nitric acid, which causes the propellant to become more corrosive toward many materials of construction.

This is the same reaction that forms the basis for the production of nitric acid on an industrial scale. When reporting the results of analyses of NTO and reporting the water content as % H_2O , one must realize that the water will most likely have reacted to form HNO_3 , which in turn forms adducts such as $HNO_3 \cdot xH_2O$ or $HNO_3 \cdot xN_2O_4$. The water should be reported as “water equivalent.”

For the quality control of NTO at the rocket test site or in the field (military applications), direct-reading methods that provide an instant readout of the results are preferred [308].

At one time, a widely used but very crude method for the estimation of water in NTO was the evaporative method given in MIL-P-26539B. The procedure is to pass a stream of dry nitrogen through a known volume of N_2O_4 at 272–273 K (28–32 °F). N_2O_4 is evaporated until the concentration of residual water exceeds its solubility and the mixture takes on a cloudy appearance. The volume is then noted and correlated with

the initial water content. This crude method requires an experienced operator to determine the end point [309].

The old military-specification procedure for water analysis was based on the evaporation of dinitrogen tetroxide at 273 K (0 °C) with dry nitrogen gas until a two-phase system was obtained. At this point the turbid residue contains 1.6% water. The percentage of water present was calculated from the volume of the two-phase residue and the starting volume. It was assumed that only dinitrogen tetroxide and nitrogen dioxide were lost when dry nitrogen was bubbled through the liquid dinitrogen tetroxide at 273 K (0 °C). This may not be such an unreasonable assumption considering that the water in the dinitrogen tetroxide is present mostly as nitric acid. However, this assumption does not allow for the possibility of mechanically carrying away some of the nitric acid as a fine mist.

An assay method for N_2O_4 (after complete oxidation of all N_2O_3 and NO) in MON described in MIL-P-27408A, MIL-P-26539C, and MIL-PRF-26539E seals a weighed amount of the oxidizer in a glass vial and breaks it under 100 mL of water and 20 mL of 30% hydrogen peroxide in an Erlenmeyer flask with a ground-glass stopper (iodine number flask). The N_2O_4 is thereby oxidized to HNO_3 , which is then titrated acidimetrically with 0.5 N NaOH using methyl red or bromothymol blue as the indicator.

For the analysis of nitric oxide-dinitrogen tetroxide mixtures, the mixture of nitric oxide and nitrogen dioxide is first absorbed in sulfuric acid, and then the sum of nitric acid and nitrosyl nitrogen in solution is determined by means of a nitrometer, and nitrosyl nitrogen is analyzed by titration with a solution of potassium permanganate [310]. A recovery of 99.8% was obtained for pure dinitrogen tetroxide and 99.8% for pure nitric oxide. For synthetic mixtures containing 4 to 10% nitric oxide, the recoveries were 99.1% for nitric oxide, 99.8% for dinitrogen tetroxide, and 99.5% for total nitrogen. The analysis is performed in a system, carefully kept free from air and water, for absorbing the gases and including a special chamber for breaking ampoules containing the samples. The method is applicable to the assay of nitric oxide, dinitrogen tetroxide, and mixtures containing up to 50 mol-% of nitric oxide.

5.8.3 Gravimetric Analysis Methods for Dinitrogen Tetroxide

Due to the poor accuracy and the time-consuming need to dry and weigh the crucibles to constant weight before the analysis, gravimetric methods would be the least favorite of any analytical chemist. Nevertheless, a gravimetric method was once described for the determination of water in dinitrogen tetroxide.

In a gravimetric method for determining small amounts of water in dinitrogen tetroxide, the vapor, in a stream of dry nitrogen, was first passed over anhydrous sodium carbonate at 553 K (280 °C) and then over metallic copper at 873 K (600 °C) [311]. Most of the acidic substances were removed by anhydrous sodium carbonate, and remaining traces of oxides of nitrogen were completely removed by

passage over hot metallic copper. The water released by these reactions was absorbed by anhydrous calcium sulfate and weighed. For samples containing about 0.5% water, the precision of the determination corresponded to a standard deviation of 0.006% absolute. At JPL, the gravimetric weighing of the adsorbed water was replaced by condensing it in a cold trap, followed by gas chromatography analysis [295].

A method in MIL-P-27408A and MIL-PRF-26539E describes a gravimetric method for determining NO in MON containing 10–25% NO. The analysis is done by weighing a sample of MON into a 60-mL stainless steel cylinder, cooling to 273 K, and feeding pure oxygen into the cylinder until oxygen absorption has stopped, thus converting all NO and N₂O₃ to N₂O₄. The percentage of NO is calculated from

$$\text{NO} = \frac{[y - 0.003857(z - \frac{x+y}{1.49})]187.5}{x} - 0.15$$

where NO = mass-% NO, x = sample mass in g, y = oxygen mass in g, and z = volume of the cylinder in mL.

5.8.4 Electrochemical and High Frequency Microwave Analysis Methods for Dinitrogen Tetroxide

The water or nitric acid content of N₂O₄ can be measured with an electrical conductivity method as long as no other contaminants are present [312, 313]. This method is suitable only for less precise measurements. For more accurate determinations of the nitric acid content, one slowly evaporates all N₂O₄ and the eventually present N₂O₃ and then titrates the remaining, non-volatile nitric acid acidimetrically with standardized sodium hydroxide solutions.

The water content of NTO or MON can be measured by determining the dielectric constant ϵ by oscillometry [314]. The dielectric constant of a material is a measure of its polarization in an electric field, which induces electron shifts in its atoms, and of the statistically preferred orientation of electrically unsymmetrical molecules in an electric field. Water has one of the highest dielectric constants, $\epsilon = 80.4$ at 293 K (20 °C). NTO has a low value, $\epsilon = 2.5$, at 288 K (15 °C), and mixtures of the two compounds have intermediate values. The wide spread between the two values permits the accurate measurement of small amounts of water in N₂O₄ as a function of the dielectric constant. The instrument was calibrated with samples containing known amounts of water up to 1.5%. In operation it is convenient to have two oscillometer cells, one for benzene with a known amount of water and the other for the N₂O₄ sample to be analyzed.

5.8.5 Optical and Absorption Spectrophotometric Analysis Methods for Liquid Dinitrogen Tetroxide

There are only a few spectrophotometric analysis methods for the measurement of assay or contaminants in liquid N_2O_4 . Most spectrophotometric methods deal with the analysis of gaseous NO_2 in air, which is summarized in Section 5.8.5.

Chloride in green dinitrogen tetroxide can be determined by ammonia absorption spectrophotometry [315].

5.8.5.1 Infrared Spectrophotometric Analysis Methods for Liquid Dinitrogen Tetroxide

The specific band assignments for contaminants in N_2O_4 are $1.470\mu\text{m}$ for HNO_3 , $1.448\mu\text{m}$ for HNO_2 , and $1.404\mu\text{m}$ for H_2O . The $1.404\mu\text{m}$ H_2O band is well resolved but is in a region where the instrumental background under high sensitivity distorts the spectrum. The $1.448\mu\text{m}$ HNO_2 and $1.470\mu\text{m}$ HNO_3 bands overlap sufficiently so that it is difficult to detect and determine small amounts of HNO_2 in the presence of larger amounts of HNO_3 .

Water (assumed to have completely reacted to form nitric acid) in liquid dinitrogen tetroxide can be determined by measuring the IR absorbance of the nitric acid overtone peak at $1.47\mu\text{m}$ [316]. Nitric oxide must first be converted to NO_2 , and all H_2O or HNO_2 must be converted to HNO_3 . The method is applicable to water contents in the 0.01–0.17 mass-% H_2O range and is capable of detecting as little as 0.002 mass-% H_2O . If HNO_2 is not completely removed, an HNO_2 absorption peak will show up at $1.447\mu\text{m}$.

Solutions of N_2O_5 , N_2O_4 , and HNO_3 in methylene chloride can be analyzed by IR spectroscopy [317].

An IR spectrophotometric method for analysis of HNO_3 in NTO and MON is described in MIL-PRF-26539E. A scan in the near-IR between 1300 and 1650 nm (7692 and 6060cm^{-1}) will reveal an HNO_3 peak. The baseline can be found by connecting the minima at 1430 and 1615 nm (6993 and 6192cm^{-1}) with a straight line. The HNO_3 peak height is measured from this slanted baseline. The absorption coefficient of HNO_3 is 0.178.

MON mixtures with NO concentrations from 1% to 5 mass-% are common in current spacecraft applications. Higher NO concentrations, as high as 30 mass-% NO, are not as common yet but are being considered for hybrid and bipropellant rocket systems to be used in future missions to/from Mars and the moon, mainly due to their low freezing points and high performance. It may be possible to analyze the NO content of MON-25 or MON-30 by FTIR of diluted, evaporated samples of this oxidizer. The analysis of different compositions of MON oxidizers was investigated using a Cary 680 FTIR spectrometer equipped with a 10-m heated gas cell. Calibration curves were obtained for NO and NO_2 by themselves before trying to analyze NO/ NO_2 mixtures [174]. Preliminary tests provided calibration curves for the main components of MON, namely

NO and $\text{N}_2\text{O}_4/\text{NO}_2$. Calibration curves showed linear variations of absorbance with concentration for both components, which was in accordance with the Beer-Lambert law and is the basic requirement for FTIR analysis as a tool to examine the quality of unknown MON compositions. For the gaseous phase, MON-X samples will have to be diluted down to at least the maximum parts per million value obtained in this study (around 500 ppm) to provide meaningful absorbance data before one can use the calibration curves for individual gases. No N_2O_3 appears to survive in the vapor phase.

5.8.5.2 UV/Visible Spectrophotometric Analysis Methods for Liquid Dinitrogen Tetroxide

Dinitrogen trioxide in N_2O_4 is measured as N_2O_3 , but it is calculated as NO by measuring its broad electronic absorption band peaking at 700 nm. At high NO concentrations, the trailing of this absorption band extends into the 1550–1350-nm near-IR region where the protonated species are measured, and corrections, therefore, must be made. Additionally, at high NO concentrations, the 700–900 nm absorbance difference is too high to be read within the 0–1.0 absorbance range available.

Analysis of mixtures containing all oxides of nitrogen is very complicated. Nitrogen dioxide and associated dinitrogen tetroxide can be determined by UV absorption at 394 nm, where other oxides of nitrogen are known to be transparent [318]. Other remaining components can later be determined by mass spectrometry.

Small amounts of nitric oxide, when dissolved in liquid dinitrogen tetroxide, exist as dinitrogen trioxide N_2O_3 . The nitric oxide content of such solutions can be determined by measuring the intensity of the green color of the N_2O_3 at 273 K (0 °C) at 700 nm. This method, described in MIL-P-26539C as an alternate method, requires a specially designed cell that is constructed of materials resistant to dinitrogen tetroxide, capable of being cooled to and maintained at temperatures near 273 K (0 °C), leak-proof under moderate pressure and vacuum, and having a path length suitable for analysis of samples containing 0–1.5% nitric oxide [319].

If a MON sample is dissolved in aqueous KOH solution in the absence of oxygen, the resulting nitrate:nitrite ratio in the aqueous solution can be determined by UV spectrophotometry and can be used to backtrack to the $\text{N}_2\text{O}_4:\text{N}_2\text{O}_3$ ratio in the original sample [320].

Chloride in NTO or MON can be determined by slowly flowing approximately 10 g of the evaporated oxidizer into a gas-wash bottle filled with 50 mL of deionized water. The solution is then rinsed into a 1000-mL volumetric flask and neutralized with concentrated ammonia to an end point determined with dinitrophenol indicator. The volumetric flask is filled to the calibration mark with deionized water and mixed. An aliquot is reacted with iron(III)ammonium sulfate and mercury(II)thiocyanate. The reaction of chloride with mercury(II)thiocyanate precipitates insoluble mercury(II)chloride and releases thiocyanate ion. The red color of iron(III) thiocyanate is

then measured in a spectrophotometer at 460 nm, and the absorption is compared to concentrations in a previously prepared calibration chart.

This method is described in MIL-P-27408A, MIL-P-26539C, and MIL-PRF-26539E. A similar method can be used to determine chloride in hydrazine.

5.8.5.3 Emission Spectrophotometric Analysis Methods for Dinitrogen Tetroxide

Most methods discussed here are absorption spectrophotometric methods. However, there are also emission spectrophotometric methods for analysis of other contaminants in N_2O_4 that are equally well applicable to oxidizers like N_2O_4 and fuels like UDMH. Excessive contamination by alkali metals in either propellant would cause a high ionization density in the exhaust plume. The plume becomes impervious to radio signals, and radio telemetry may be disturbed by radio wave attenuation. The alkali metals in NTO can be determined by flame spectrophotometry [321]. Nowadays the same would be done more accurately with inductively coupled plasma emission instead of flame emission spectrophotometry.

The iron content of NTO can be determined by atomic absorption spectroscopy using the 248.8-nm resonance line of Fe [322]. A linear calibration chart was created for iron concentrations up to 6 ppm. The sensitivity for iron in NTO was five times better than that for iron dissolved in water.

5.8.5.4 Gas Chromatographic Analysis Methods for Dinitrogen Tetroxide

Because nitrogen dioxide reacts with most organic oils and porous polymers used as stationary phases in gas chromatography, it has been proposed to convert all NO_2 to HNO_3 and NO by reacting it with water that is pre-adsorbed on the surface and in the pores of a molecular sieve column [323]. NO does not react with most stationary phases/partitioning liquids used in gas-liquid chromatography. One mol of NO is formed for each three mols of NO_2 converted. The HNO_3 remains adsorbed on the molecular sieve along with the water. Oxygen has to be excluded from the sample gas and the carrier gas.

An electron capture detector was used in a gas chromatograph to measure parts per million quantities of nitrogen dioxide in a ternary mixture of nitrogen, oxygen, and nitrogen dioxide [324]. For concentrations of nitrogen dioxide from 5 to 150 ppm and for oxygen present to the extent of 9% by volume in nitrogen, the standard deviation of the best calibration curve through the points showing response versus concentration was 2 ppm, compared to about 3 ppm for wet chemical techniques. The main advantages of gas chromatography are the short time for analysis and the small sample size (0.5 mL) required.

Liquid dinitrogen tetroxide can be analyzed for water content by passing it through hot copper shavings at 1073 K (800 °C) contained in a column wherein all nitrogen-containing and hydrogen-containing compounds including HNO_3 and HNO_2

are converted quantitatively to dinitrogen and water [325, 326]. The effluent from the column is then passed into a gas chromatograph and separated on a Porapak-Q column, where the amount of water initially contained in the nitrogen tetroxide can be determined by integrating the area under the peak or, for narrow peaks, by the peak height method. Less than 10 minutes is required for an analysis, and as little as 0.1 g of water (0.01 mass-%) can be determined reproducibly. Organic compounds or dissolved carbon dioxide in the sample can also be determined by this method. If there are organic contaminants, the H_2O content detected must be corrected for H_2O resulting from the combustion of organic contaminants.

The gas chromatographic determination of water content in NTO or MON is fraught with uncertainties about the form in which the water exists in the oxidizer, most of it being in the form of HNO_3 , which is difficult to run through a gas chromatograph without decomposition and corrosion [307].

Another method to determine NO, CO_2 , N_2O , and NOCl in dinitrogen tetroxide has been suggested [327].

5.8.5.5 Mass Spectrometric Analysis Methods for Dinitrogen Tetroxide

During an effort to identify contributors to metal corrosion, the analysis of non-volatile residue in MON was hampered by the small amount of residue available for analysis, only 10–20 mg/L. Subsequently, the inlet of a mass spectrometer was modified to facilitate sample handling and to analyze the samples for NO content [328]. A method was developed to determine nitric oxide in N_2O_4 using a mass spectrometer. This was accomplished by some modification of the inlet system on the instrument and by the development of suitable handling techniques that prevented the loss of NO.

5.8.5.6 Nuclear Magnetic Resonance Analysis Methods for Dinitrogen Tetroxide

Researchers at the JPL developed an NMR procedure for the rapid quantitative analysis of water in dinitrogen tetroxide and MON oxidizers [195]. This technique was capable of detecting as little as 0.001 mass-% of H_2O (10 μg of water per gram of propellant) and gave results in the concentration range of 0.01–0.02 mass-% with a precision of about ± 0.002 mass-%. Because many samples of NTO/MON contain NO, a separate procedure for oxygen titration of NO prior to NMR analysis for H_2O was developed that gave the NO concentration accurately to within ± 0.05 mass-%. While this method employed the continuous wave method at modest magnetic field strengths, equivalent to resonance at up to 100 MHz, a newer method based on high-field Fourier transform proton NMR offered greatly improved sensitivity suitable for the determination of lower water contents. The newer method used a 250-MHz Fourier transform proton NMR and an internal proton-containing standard, deuteroacetonitrile, HD_2CCN with a known content of 1H, and it was able to analyze water down to 0.003 ± 0.0012 mass-% [329]. Dideuteroacetonitrile is chemically inert to N_2O_4 , but solutions of HD_2CCN in MON

are less stable than those in NTO. Because this method is an absolute method, it does not require calibration prior to analysis. Unlike previous NMR methods, paramagnetic NO does not have to be oxidized prior to analysis. The sample temperature during NMR measurement is not critical; it can be anywhere between 268 and 294 K. The deuteroacetonitrile used as internal standard was 99.5% D₃CCN and contained only a known trace of HD₂CCN. The H proton in HD₂CCN produced a non-binomial quintet at 1.93 ppm. The analysis was performed by distilling a known mass (40 μ L) of dideuteroacetonitrile in trideuteroacetonitrile into frozen NTO at 77 K and sealing the NMR tube. The NMR tube was allowed to warm slowly to room temperature and was then ready for analysis.

NMR spectra were determined for four N₂O₄ samples scanned from 0 to 10 ppm at room temperature [328]. Trimethylsilane was used as the external standard to determine the 0-ppm line, but it could not be used as an internal standard because it reacted with the samples. All samples exhibited one absorption between 8.5 and 11.0 ppm, which was probably from water protons in a highly electronegative environment such as would be provided by NO₂. It would be necessary to introduce an internal standard to determine any variations from one sample to the next.

A comparison of various analysis methods to determine the equivalent water content in dinitrogen tetroxide included gas chromatography, near-IR spectrometry, microwave, and NMR methods. The theory and the application of NMR methods were emphasized in this paper [330].

Equivalent water content in nitrogen tetroxide was determined by NMR spectroscopy (NMRS) using deuteroacetonitrile as internal standard [331]. The linearity range of the method was steady over 0.004–0.39% H₂O. The detection limit (3σ) was $1 \times 10^{-4}\%$. Relative deviations between the results found by the NMRS method and those found by gas chromatography were $\sim 3.8\%$. See also [332, 333].

Electron spin resonance (ESR) studies indicated the presence of several paramagnetic substances in the N₂O₄ samples, which made it very difficult to interpret ESR and NMR spectra.

5.8.6 Rapid Liquid Propellant Analysis Methods for Use in the Field

Rapid analysis methods are needed for use in the field to give a quick go/no go answer about the acceptability of a propellant for a given application [334]. Ideally this would be in the form of a dipstick probe with a direct readout.

Any launch vehicle delay or stacking mishap could potentially lead to the necessity to off-load the propellants from a satellite. This propellant would have to be returned into its transport container. Any off-load operation can potentially compromise the propellant composition, and in this situation, at remote launch sites in Eastern Europe or Asia or on floating launch platforms, there would be no way of determining

any contamination in the propellant without flying a propellant sample back to the home base in Europe or the United States, where chemistry labs with the necessary equipment and operator experience can do an accurate analysis. It was proposed to establish a portable modular laboratory capable of analyzing MON, N_2H_4 , and MMH that could be flown to the remote launch sites where no chemistry laboratory support was available. The mobile laboratory would have to be robust to allow for air transport and be minimal in size to reduce transport costs [335]. The instrumentation would be designed and modified to fit into standard-size air freight cases of approximately 1 cubic meter each, with a maximum of five flight cases required for a “complete” lab.

5.8.7 Analysis of Nitrogen Dioxide in the Air at the Work Place

Dinitrogen tetroxide that leaks into the work room air will quickly evaporate and dissociate into nitrogen dioxide, readily visible by its reddish-brown color. Work room air-analysis instruments for audible alert systems or continuously recording record-keeping are described in the chapter on nitrogen dioxide. In addition to active leak detectors that sound an alarm if a leak is detected, passive leak detectors such as color-changing paint will not only alert the observer but also locate the leak.

5.8.8 MIL and NASA Specifications

The AIAA Special Report [209] contains a first-hand historical account of the evolution of specifications for NTO and MON, quoted here:

One of the original applications for NTO as a rocket oxidizer was the Titan II intercontinental ballistic missile that used brown NTO. About the same time, NASA required an NTO with a lower freezing point for space missions. The requirement led to specifications MIL-P-27408A (1971) for NTO products designated MON-10 and later MON-25 that contained 10 and 25 mass-% nitric oxide, respectively. Sometime later NASA found in the Apollo program, that serious stress-crack corrosion problems occurred with titanium hardware when NTO that contained no nitric oxide was used. To overcome this corrosion problem, NASA created a specification (MSC-PPD-2 and later MSC-PPD-2A) for NTO similar to the military specification except for a requirement that the product contain $0.65 \pm 0.2\%$ nitric oxide (MON-1) to inhibit titanium stress crack corrosion. MSC-PPD-2 and later MSC-PPD-2A were incorporated into the military specification, MIL-P-26539C [336]. When the Minuteman ICBM was developed, the decision was made to use a prepackaged (sealed) liquid bipropellant propulsion subsystem for the fourth stage. The oxidizer chosen was an NTO formulation that contained 0.31 ± 0.2 mass-% nitric oxide designated by Bell Aerosystems as *Minuteman Grade*, Bell Specification 8477-947041. This nitric oxide level was selected to provide an additional margin of safety for long-term storage in stainless steel tankage [337]. Early in the development of the small bipropellant engines for Shuttle reaction control it was determined that the level of nitric oxide should be greater than that for MON-1 to allow for losses caused by repeated depressurization of storage vessels. This led to a decision by NASA to introduce another formulation of NTO containing 2.75 ± 0.25 mass-% nitric oxide, MON-3, which was incorporated

into MIL-P-26539C as Amendment 1. The result of the decisions by various organizations lead to the brief existence of at least five different specification documents for the various NTO formulations in use. The Aerospace Industries Association of America, a group of industrial organizations with a common interest in rocket propulsion, volunteered to consolidate the specifications for brown NTO, MON-1 and MON-3. The efforts resulted in a National Aerospace Standard, NAS-3620 [338], which contained all the requirements and the most recent analytical methods for three formulations of NTO used by the military and NASA [338]. Several years later the Air Force produced a military specification, MIL-P-26539D, a consolidation of NAS-3620 and the military specifications for MON-10 and MON-25.

The performance specification MIL-PRF-26539F is the current (2014) documentation used by the U.S. Department of Defense (DOD) and NASA for NTO procurement [339]. European space agencies and their contractors have developed their own set of propellant specifications for MON [340]. Table 40 is a summary of current and past (expired) propellant specifications for NTO and MON.

Table 40: Current and former military specifications for NTO and MON

Designation	Date issued	Date canceled or superseded	Propellants covered	Remarks
MIL-P-26539C	30 Mar 1970		NTO and MON-1	[336]
MIL-P-26539C amendment 1	1 Mar 1971			
MIL-P-26539C amendment 2	5 Apr 1976		NTO, MON-1, and MON-3	
MIL-P-26539D	28 Aug 1989	7 Oct 1997		
MIL-PRF-26539E	7 Oct 1997	17 Apr 2006	NTO, MON-1, MON-3, MON-10, and MON-25	
MIL-PRF-26539F	17 Apr 2006		NTO, MON-1, MON-3, MON-10, and MON-25	Maximum allowed iron content is 0.5 ppm
MIL-P-27408	31 Jul 1964		MON-10 and MON-25	
MIL-P-27408A	15 Oct 1971	6 Sep 1989	MON-10 and MON-25	[341]

Table 41 lists the purity requirements of NTO and MON according to MIL-PRF-26539F.

Table 41: NTO and MON specification requirements per PRF-26539-F

Composition Color	NTO Reddish- brown	MON-1 Green	MON-3 Green	MON-10 Green	MON-15 Green	MON-25 Green	Test paragraph
N ₂ O ₄ assay, %wt, MIN	99.5	—	—	—	—	—	4.3.3
NO content, %wt, MAX	*	1	3	11	16	26	4.3.2
NO content, %wt, MIN		0.6	2.5	10	15	25	
N ₂ O ₄ + NO, %wt, MIN	99.5	99.5	99.5	99.5	99.5	99.5	4.3.3
Water equivalent, %wt, MAX	0.17	0.17	0.17	0.17	0.17	0.17	4.3.4
Chloride content, %wt, MAX**	0.04	0.04	0.04	0.04	0.04	0.04	4.3.5
Non-volatile residue, mg/L, MAX	—	10	10	10	10	10	4.3.6
Iron content, ppm wt, MAX	—	0.5	0.5	0.5	0.5	0.5	4.3.7
Particulate, mg/L, MAX	10	10	10	10	10	10	4.3.8

* The NO content shall be limited to that which does not change the specified reddish-brown color of the propellant

** The chloride test does not need to be performed on any propellant type if the material was manufactured using the ammonia oxidation process

5.8.9 Round-Robin Analysis Results

An industry-wide and government-wide round-robin analysis exercise for military-specification and NASA-grade MON showed the need to standardize the methods and equipment in order to obtain reproducible and comparable results [342]. Twenty-two stainless steel cylinders were fitted with two valves on either end and were passivated with MON-3 for 20 weeks. Then 11 were filled with MON-1 and another 11 were filled with MON-3, and they were sent to participating laboratories to be analyzed for N₂O₄ assay, chloride, water, NO, and iron in triplicate as prescribed by NAS-3620. The results, reported by ten laboratories, were analyzed using statistical methods. Chloride analyses had the least outliers of any method. The iron analysis showed good repeatability within a laboratory but poor reproducibility between laboratories. The NO analysis had inhomogeneous variances for both MON-1 and MON-3, and two laboratories reported results that were outside the 95% confidence interval.

Since April 1996, dinitrogen tetroxide tank cars have been sampled and analyzed as soon as they arrive at NASA Kennedy Space Center and prior to passing the oxidizer

through a molecular sieve filter in preparation for loading on the Space Shuttle orbital maneuvering and reaction control systems [343]. Significant discrepancies were sometimes noted between NASA’s results and the manufacturer’s certification accompanying each shipment. Sometimes the propellant was “out of spec,” most often due to low NO content.

6 Materials of Construction for Dinitrogen Tetroxide

The presence of a few tenths of a percent of water in NTO or MON leads to rapid corrosion failure of containing metals. For all applications, the water content must be carefully controlled.

Dinitrogen tetroxide with and without the addition of small amounts of N₂O₃ is the most important storable oxidizer; consequently, a lot of work has been conducted to select the proper materials of construction. The following summaries in Table 42 provide a good starting point in the study of this topic. Most of the publications date back to the time when the Titan-II ICBM was developed and fielded in launch silos. Some of these reference publications need to be on the bookshelf of any spacecraft designer working with storable bipropellants.

A design guidebook on material compatibility with space storable propellants contains sections on NTO/MON and also sections on MMH, B₂H₆, F₂, OF₂, and FLOX [355].

6.1 Compatibility Test Methods

Methods for testing the compatibility of existing and new materials of construction have been developed over the years by either the manufacturers of the propellants or by the rocket propulsion industry and government laboratories in support of the user community. This applies to materials testing for compatibility with NTO in particular because it is one of the more corrosive oxidizers.

In the 1960s it was considered necessary to standardize immersion test methods used at the many different laboratories throughout the United States, and the American Society for Testing and Materials (ASTM) issued specifications describing recommended methods for testing with dinitrogen tetroxide and its blends with dinitrogen trioxide [356].

A standardized test for the gross compatibility of materials with NTO as a function of exposure time and temperature is the immersion test described in *Reactivity of Materials in Aerospace Fluids (Test 15)* (NASA 1991). The unstressed material is immersed in NTO liquid at 344.1 K (160 °F) and is held for 48 h or until the pressure exceeds the normal vapor pressure of the NTO at the test conditions. Following the immersion, the samples are examined for weight loss, changes in surface appearance, and tensile properties.

One of the visually most explicit methods to study corrosion of metals at the molecular level is the use of a scanning tunneling electron surface microprobe [357].

Liquid-fueled missiles in submarines have been the cause of numerous submarine accidents in the Russian fleet (e.g., K-219, Project 667A in 1986). Corrosion is an important factor in missile reliability. Therefore, corrosion testing of the materials used to build these missiles has to be done beforehand, and it would be desirable to accelerate these tests in the laboratory. The service environment of submarine-launched missiles may directly affect their life span. An equivalent conversion method is used to establish the relationship between the corrosion equivalent acceleration and actual corrosion. A three-dimensional digital video microscope was adopted to observe the corroded surface of the metal specimens [358].

6.2 Corrosion of Metals in Dinitrogen Tetroxide

The selection of metals for propellant tanks and components that will be wetted by NTO or MON for long periods of time (decades) requires a thorough understanding of the mechanism of corrosion and the roles played by various contaminants in the oxidizer. There is sufficient published information on the corrosion of metals by NTO/MON to fill a book in its own right. Only a sampling of the most prominent publications in the available literature is offered here.

Some of the Material Safety Data Sheets for N_2O_4 written by chemical suppliers state, “Anhydrous nitrogen dioxide is non-corrosive to most metals at normal temperatures. It does corrode copper and its alloys.” This is surprising, considering the many corrosion problems the aerospace industry has had in dealing with this oxidizer. This statement was probably written by a marketing representative and not by a chemist.

6.2.1 Corrosion Mechanisms in Dry or Moist Dinitrogen Tetroxide or MON

The reaction that takes place in moist NTO in contact with metals is due to the formation of nitric acid from N_2O_4 and H_2O :

The nitric acid then will attack the metal and form metal nitrates and their adducts with N_2O_4 or H_2O :

Because water and nitric acid are regenerated during some of the reactions, the corrosive attack will continue indefinitely [359]. The corrosion products can be in solution or in suspension in the NTO or MON oxidizer. The solubility of the corrosion products increases with the NO content of the oxidizer. A recognized method for recovery from flow-decay problems in an operating system is to raise the propellant temperature so that the contaminants go back into solution and remain in solution.

The corrosion of chromium/iron-alloys (50–80% Cr) by NTO at 300–400 K and 0.1–16 MPa results in the formation of an oxide crust layer consisting of the oxides of both elements [360]. The rate of corrosion is distinctly higher than that of Cr-Ni-Mo steels such as the Russian 09Kh16N15M3B. Annealing of the Cr/Fe steel at 1170 K can change the alloy structure and reduce the rate of corrosion, but only by a small amount. At higher temperatures (870–1270 K), the corrosion results in the formation of solid and volatile chromium oxides. The dominant effects on the rate of corrosion are due to the original O, N, and C content of the alloy.

6.2.2 Corrosion Effects of Chloride in Dinitrogen Tetroxide or MON

Chloride inadvertently introduced into dinitrogen tetroxide during manufacturing or transfer may accelerate corrosion of stainless steels and may cause stress corrosion in titanium alloys. Some degreasing solvents contain chlorine, and residues of degreasing solvents in a system that is later filled with NTO or MON will cause serious problems.

Chloride introduced as HCl or FeCl₃ will first be oxidized to free chlorine and then quickly convert to nitrosyl chloride NOCl, which is very volatile (boiling point 267.6 K [−5.5 °C]) and is totally soluble in NTO or MON.

The presence of chloride will accelerate the rate of iron solution from stainless steel in NTO or MON. Since the chloride is regenerated in the process, one atom of chloride will be responsible for dissolving many atoms of iron. Once the concentration of Fe(NO₃)₃•1.5N₂O₄ exceeds saturation, flow-decay problems may ensue.

Specifications MIL-P-26439D or NAS-3620 limit the amount of allowable chloride to 0.040% (400 ppm) maximum. It was surprising to see that a number this high is allowed. It seems that some NTO/MON users have instituted tighter chloride limits at the point of end use. There have been discussions about lowering the tolerable chloride levels in future revisions of the specifications.

It seems there were some incidents in which residual cleaning fluids (Freon-TF, Freon-PCA) contributed to metal corrosion in both NTO and hydrazine. Sometimes bromide may also have been present and was not recognized as such. Bromide would be just as bad as chloride. There would be no impact on propellant performance as long as chloride content does not exceed the specification limits. See also [361].

Chloride and other impurities have a pronounced effect on the corrosivity of N₂O₄ toward metals [300]. Water in N₂O₄ caused severe corrosion of Al-6061 or CRES-347, while the effect of NOCl or Cl[−] impurities on unstressed specimens was negligible. Ti-6Al-4V was much more resistant to attack by N₂O₄ than the other two metals. Possible corrosion mechanisms were proposed.

6.2.3 Electrochemistry of Corrosion in Dinitrogen Tetroxide or MON

Corrosion of metals is an electrochemical process that is enhanced in the presence of galvanic couples of elements with different electronegativity or where metals are separated by phase segregation in the heat-affected zone of welds. The difficulty with measuring polarographic potential in N₂O₄ is that the electrical conductivity of the electrolyte is very low, often below the threshold of sensitivity of commercially available potentiostats. Since 1978, advances in electrochemical instrumentation have enabled short-term, accelerated tests. The idea of using electrochemical techniques to study corrosion phenomena follows from the fact that corrosion phenomena can be explained in terms of electrochemical reactions. A unique advantage of electrochemical techniques is that they can yield kinetic and mechanistic information about processes occurring at the interface between material and solution. The electrochemical

information is obtained in a relatively short time and can subsequently be used to predict corrosion rates and compatibility.

The application of electrochemical compatibility test methods to metals exposed to N_2O_4 was difficult because it was found that pure N_2O_4 is not sufficiently conductive to permit electrochemical measurements to be carried out [192]. Researchers used electrochemical measurements in a limited potential region and showed that the polarization resistance measurements were in good agreement with the corrosion rate data obtained by weight loss and solution analysis for long-term tests. It was necessary to add an excessive amount of water in the concentration range of 10–11 mass-% in order to obtain compatibility data via the electrochemical method. This concentration corresponds to the high-density acid phase of the $\text{N}_2\text{O}_4/\text{H}_2\text{O}$ system. Above 1–2 mass-% water, a small portion of the high-density acid phase is formed, which can produce localized corrosion. It was suggested that corrosion in the high acid phase should be considered for further study even though the overall water concentration was quite low.

Electrochemical techniques for evaluating the long-term compatibility of liquid propellants in various containment materials require that the liquid and containment material be electrical conductors, that the exchange current be measurable, and that the propellant decomposition mechanism be known [362]. The time base can then altered by electrolysis of the system at some multiple of the natural decomposition rate. As a result, a simulated time scale can be achieved in which the propellant decomposition rate can be predicted for up to 15 years, while the actual time required for the tests is on the order of only 1–2 months, depending on the particular metal tested.

Electrochemical impedance spectroscopy was tested as a useful tool for the study of corrosion in electrolytes, even poorly conducting electrolytes such as dinitrogen tetroxide and hydrazine [363–366]. Although the methods in poorly conductive media like hydrazine operate at the limit of sensitivity for commercially available potentiostats, the selection of proper electrode geometry and the application of interrupter and feedback techniques enabled researchers to gain insight into the electrochemical processes leading to corrosion at the electrolyte-metal interface. The tests included CRES-430 with MON-1 spiked with water (0.19% H_2O), giving a conductivity high enough to permit some direct current (DC) measurements required for determination of approximate Tafel slope values, as well as the alternating current (AC) measurements, CRES-304L with MON-10 and Al-6061 with the same “MON-1” (actually NO-1.6%) oxidizer. In all cases, the electrochemical values for corrosion rates agreed to better than an order of magnitude with the (not exactly comparable) results from standard metal dissolution analysis, results that became available only after a much longer exposure time.

Theoretical studies predicted that with stainless steel/titanium couples immersed in NTO, the iron would act as a sacrificial anode, protecting the titanium it is in contact with. This would result in large amounts of iron going into solution but eventually exceeding the solubility in NTO and causing flow decay. A study of the corrosion of com-

ponents of a surface-tension PMD in the Intelsat VII propulsion subsystem used AC impedance measurements, immersion tests with chemical analysis of off-loaded propellant, and surface examination of exposed specimens to ensure the compatibility of the tank and its PMD with MON-3 for a 7-year satellite mission [367]. The following components were tested by themselves and in electrical contact with the other metal:

- CP Ti screen
- CRES-304L screen
- CP Ti foil (frame) attached to CP Ti screen
- CP Ti foil (frame) attached to CRES-304L screen
- Ti-6Al-4V tubing
- CRES-304L tubing
- Ti-6Al-4V tubing attached to CRES-304L tubing

All tests were conducted at 305 K (32°C; 90°F) and continued in three batches for 44, 90, or 180 d. The surface-to-volume ratios depended on the geometry of the specimens being tested, and they varied widely. The off-loaded propellant was filtered through a stack of Teflon filter membranes in which the first filter's pore size was 5 μm and the second and third filters' pore size was 0.2 μm . The exposed metal specimens were examined by optical microscope, scanning electron microscopy (SEM), electron spectroscopy for chemical analysis (ESCA), and Auger. Auger electron spectroscopy was done repeatedly on the same area of the specimen after intermittent ion etching to obtain element concentration profiles through the surface layers. Altogether, the tests demonstrated that the materials selected were satisfactory for the intended 7-year mission. Theoretical studies predicted that iron in contact with titanium alloys would act as a sacrificial anode, protecting titanium. The main concern was whether the iron concentration would exceed the solubility limit before the end of the 7-year mission.

Electrochemical methods for accelerated compatibility measurements of metals in NTO, MON, or nitric acids are DC polarization and AC impedance measurements [368]. These methods are supplemented by visual examination of corroded specimens under an optical microscope or by SEM, Auger, and ESCA surface analysis methods [369].

6.2.4 Corrosion Inhibitors for Dinitrogen Tetroxide

MON is used instead of pure NTO to prevent stress-corrosion cracking in titanium and steel tanks. Stress corrosion can be avoided by adding N_2O_3 to N_2O_4 .

In analogy to IRFNA, initial plans were to inhibit corrosion in NTO by adding a fluorine-containing oxidizer, F_3NO , but storability results showed that F_3NO is not compatible with NTO at elevated temperatures [370]. FNO_2 was substituted as the inhibiting fluorine oxidizer, and this propellant system was then called INTO-2. Its constituents were found to be compatible in the short term with most metals at 343 K (70°C), and long-term and short-term corrosivity tests were initiated. Results of 7-d

compatibility tests with non-metallics were completed in NTO, INTO-1, and INTO-2 and indicated that INTO-2 was more compatible than INTO-1 with the materials studied. There was little difference between NTO and INTO-2. INTO-2 was prepared by the reaction of fluorine with NTO. Fluorine reacts with water, and the resulting mixture was shown to react with intentionally added water, bringing the water equivalent down to 0.03 mass-%.

Corrosion tests of steel and aluminum alloys were conducted in wet NTO, dry NTO, and dry NTO + HF at ambient temperature for 30 d and for 20 months, and at 343 K (70 °C) for 30 d [371]. A definite passivation layer was noted both visually and by weight change on the aluminum samples exposed to INTO made from dry NTO. Storability tests of INTO in stainless steel, aluminum, and nickel containers at 343 K (70 °C) for 4 months showed no apparent change in the composition of the propellants. The electrical conductivity of INTO prepared from wet and dry NTO was 3.4×10^{-11} and $4.0 \times 10^{-11} \text{ ohm}^{-1} \text{ cm}^{-1}$, respectively.

Storability tests were conducted on INTO-2 at ambient temperature and at 343 K (70 °C) in aluminum and iron tanks of 10 to 18-gallon volume [372]. Two 24-gallon titanium 6Al-4V tanks that were to be tested during the program failed while fluorine was being bubbled into them to form FNO₂. This indicated that INTO is not storable in titanium 6Al-4V when formed *in situ*. Titanium 6Al-4V specimens were uniaxially stressed to 90000 psi and stored in INTO at ambient temperature and 343 K (70 °C) for 43 d. Stress-corrosion failure did not occur.

Detonation propagation, U-tube adiabatic compression, and drop-weight impact testing sensitivity tests of solutions of 3 and 8 mass-% FNO₂ in NTO were negative [373, 374]. Tensile elastic moduli were determined on stress-corrosion test specimens of 250 maraging steel, 347 stainless steel, and 2219 aluminum immersed in INTO, and samples of the same metals were exposed to INTO while stressed at 75% of their yield strengths. Atomic absorption methods were developed to analyze INTO and NTO for dissolved Fe, Cr, Cu, Ni, Ti, and Al, and detection limits for these six elements dissolved in NTO were improved four-fold.

Inhibited dinitrogen tetroxide (INTO) is N₂O₄ containing 1–3 mass-% FNO₂. The storability of INTO was investigated at room temperature and 343 K (70 °C) in tanks of 10 to 24-gallon capacity made from CRES-347, carbon steel 1018, maraging steel 250, Al-2219, Al-2014, and Ti-6Al-4V [375]. For the large tank storability tests, NO₂F was prepared *in situ* by bubbling difluorine gas directly into crude NTO that contained 0.22 mass-% H₂O equivalent and thus was deliberately out of spec. The *in situ* method for NO₂F addition introduced other problems and was abandoned after it was found that the tanks were not as well protected by INTO as earlier small-scale tests that had not used the *in situ* method had indicated. The rate of *in situ* formation of FNO₂ by the addition of F₂ to wet N₂O₄ was slower and more difficult than had been anticipated. Small-bomb storability tests in bomblets made from maraging steel 250, A286 steel, and Ti-6Al-4V were conducted with two INTO samples prepared from NTO that originally contained 0.08 mass-% H₂O or 0.2 mass-% H₂O, respectively. INTO was found

to be storable in A286 (14 months, ambient, and 343 K) but not in maraging steel 250 or Ti-6Al-4V. Additional small-bomb compatibility tests at ambient (25 months), 343 K (25 months), and 403 K (49 h) indicated that INTO was storable in CRES-304L, CRES-321, Al-6061, or nickel when the containers were sufficiently passivated. Stress-corrosion tests were conducted with two uninhibited propellant-grade NTOs, MIL-P-26539 and MSC-PPD-2A, but none of the samples ruptured.

Two 50-gallon batches of INTO were field-prepared, but severe tank corrosion and iron fluoride precipitation occurred, resulting in clogged feed lines and flowmeters [376]. Although rocket engine performance with N_2H_4 , MHF-3, or Ae-50 was not degraded by the inhibitor, the corrosion problems and physical properties made the use of INTO impractical for future Air Force applications. It was concluded that FNO_2 in 3–5% concentrations did not affect the performance of NTO when combusted with hydrazine, Aerozine-50, or MHF-3. INTO should be filtered between preparation and its addition to storage tanks, and it should be stored in unvented systems and assayed after any venting process because of the high evaporation rate of FNO_2 .

Only five of the corrosion inhibitor candidates were found to have some effect in reducing the corrosion of stainless steel, aluminum, or titanium in N_2O_4 [309]: phosphorus trifluoride, phosphorus pentafluoride, ammonium fluorosulfonate, potassium fluorosulfonate, and tetramethylammonium tetrafluoroborate.

Phosphorus pentoxide has been patented as a corrosion inhibitor for magnesium alloys in N_2O_4 [377]. However, ammonium hexafluorophosphate caused increased corrosion and was not suitable as an inhibitor.

6.3 Flow Decay in Dinitrogen Tetroxide

Corrosion products in NTO, mostly iron leached from the wall or screen in steel tanks and their PMDs, may initially remain in solution but will precipitate when the concentration exceeds the saturation level or the oxidizer tank cools down. Salts may also precipitate in high-shear flow with high-flow velocities. Suspended particles, often in the form of a gelatinous mass, may clog small flow passages such as in filters, metering orifices, and injector passages. The resulting restriction of flow passages causes increased pressure drop and reduced flow. This problem of flow decay received a significant amount of attention during a 2-decade period toward the end of the last century.

While much has been written and discussed about flow decay, what is missing are accurate accounts of problems with flow passage obstruction during ground testing and flight use. It is unknown how many satellites or space probes have encountered this problem in flight and subsequently had their mission cut short or had to have the spacecraft switch to a backup system sooner than expected. The problem would be encountered mostly with small bipropellant thrusters with thrust levels at or below

22N, and then only after the mission had already been in progress for some time, and not so much with 400-N engines that are often used for orbit insertion, midcourse correction, and apogee kick stages.

In 1965, a valve with a window into the area of the valve seat was flowed with NTO until a deposit between the seat and the needle could be observed and correlated with the flow decay. That was the first time the problem had been visualized. Flow decay could be induced at will by soaking the propellant tank at 311–319 K and then dropping the temperature at the same time when the flow test was started. In trying to identify the mechanisms leading to the formation of injector-clogging flow-decay-causing materials and in the search for a magic solvent that would dissolve the precipitates or prevent their formation in the first place, iron(III) nitrate complexes with N_2O_4 as an adduct with compositions similar to $\text{Fe}(\text{NO}_3)_3 \cdot n\text{N}_2\text{O}_4$ were synthesized in the laboratory by reaction of $\text{Fe}(\text{CO})_5$ with N_2O_4 and were compared with contaminants collected from actual propulsion subsystems [378, 379]. One of the samples analyzed was $\text{Fe}(\text{NO}_3)_{3.19} \cdot 1.03\text{N}_2\text{O}_4$. It was suspected that the deposits might also contain water, and NMR and EPR spectroscopy were used to search for water in the deposits. The $\text{Fe}(\text{NO}_3)_3 \cdot n\text{N}_2\text{O}_4$ adduct was soluble in acetonitrile, ethyl acetate, nitromethane, nitrobenzene, acetone, and acetophenone. Acetonitrile was compatible with N_2O_4 , but nitromethane was not.

Flow decay causing corrosion products can take the form of either a solid or a second liquid phase, the latter being ambiguously described as very viscous or gelatinous but sufficiently stiff to clog orifices [380]. Both types of deposits are derived from iron nitrate, the solid being assigned the chemical formula $\text{NOFe}(\text{NO}_3)_4$, the liquid being a complex mixture derived from the interaction of iron nitrate and water. Both are soluble in dinitrogen tetroxide, but only at a level of a few parts per million (as iron). Their presence in the propellant and their deposition are a function of the water-equivalent level of the propellant and of the temperature and pressure profiles that the propellant encounters before and during flow. In general, the deposition will occur whenever propellant has been cooled just prior to or during flow, and this change in temperature to bring about contaminant deposition and flow decay may be as small as 1–2 K (3–5 °F). It was found that the presence of excess water in amounts up to the general-use limit of 0.2% changed the characteristics of the deposits formed when NTO was heated and then cooled prior to or during flow [381]. Instead of the crystalline solid $[\text{NOFe}(\text{NO}_3)_4]$ that is deposited from dry propellant, gelatinous or viscous liquid phases were formed in wet propellant. The appearance of these deposits was governed by an equilibrium solubility limit similar to that observed for the solid deposits in dry propellant. The gelatinous or viscous liquid deposits were not observed to adhere to or plug valves and orifices, as did $[\text{NOFe}(\text{NO}_3)_4]$, but they did clog filters. Flow-decay concerns affected the propulsion system selection for a planned orbital workshop, a small-scale manned space station forerunner [382–384].

Flow-decay studies performed by TRW Systems Group examined clogging materials not only in NTO but also in hydrazine, oxygen difluoride, and diborane, all in the category of space-storable propellants [385–387].

A flow-decay study was performed on the feed lines, valves, and filters of a bipropellant propulsion subsystem intended for an early version of a manned space station called Orbital Workshop [384]. The system was exposed to off-limit (high and low) temperatures and fed with normal and artificially aged propellants. Engine flow decay due to increased pressure drop did not exceed 10% of the nominal flow rate when tested with military-specification-grade NTO and did not exceed 5% of the nominal flow rate when tested with artificially aged and temperature-cycled NTO.

The rate of dissolution of iron or chromium from steel in N_2O_4 and the solubility limit of corrosion products as a function of temperature, as well as the effects on the rate and solubility of adding small known amounts of the impurities H_2O , NOCl , and NO , were measured using a radioactive tracer technique by thermal neutron activation followed by γ -radiation counting [388–392]. It was found that N_2O_4 reacts initially with metallic iron to form a surface layer of iron nitrate, whereupon the iron nitrate dissolves in N_2O_4 . The detection limit was 0.1 ppm for iron, 0.01 ppm for zinc, and 0.001 ppm for chromium. In addition to metals leaching into NTO, metals leaching into anhydrous hydrazine were measured using the same method. See also [393].

The behavior of $\text{Fe}(\text{NO}_3)_3 \cdot n\text{N}_2\text{O}_4$ adducts has been studied in HNO_3 solution and in $\text{HNO}_3/\text{N}_2\text{O}_4$ mixtures, since the presence of HNO_3 in propellant N_2O_4 was suspected to influence the physical and chemical nature of the flow-decay deposit and may be partially or perhaps primarily responsible for corrosion of steel [394]. The properties of the $\text{Fe}(\text{NO}_3)_3 \cdot n\text{N}_2\text{O}_4$ and $\text{HNO}_3/\text{N}_2\text{O}_4$ system were interpreted in terms of a gross modification of the $\text{HNO}_3/\text{N}_2\text{O}_4$ phase diagram by $\text{Fe}(\text{NO}_3)_3 \cdot n\text{N}_2\text{O}_4$. A flow apparatus was then constructed so that flow-decay deposit could be collected and its chemical identity and physical form studied as a function of the “water” (HNO_3) content of the N_2O_4 analyzed (as monitored by NMR). The dissociation vapor pressures of $\text{Fe}(\text{NO}_3)_3 \cdot n\text{N}_2\text{O}_4$ were measured to elucidate the stoichiometry of stable adducts, and SEM of crystals was done before and after exposure to dilute solutions of NOCl in liquid N_2O_4 for known lengths of time. The IR spectrum of the initial (un-evacuated) $\text{Fe}(\text{NO}_3)_3 \cdot n\text{N}_2\text{O}_4$ showed a very intense band at 2230 cm^{-1} (Figure 47a), together with the expected bands due to molecular N_2O_4 . On evacuation of the compound (10^{-2} mm Hg) for 3 d, the molecular N_2O_4 bands and the band at 2230 cm^{-1} decreased in intensity, and a further band appeared at 2298 cm^{-1} (Figure 47b). After evacuation for a further 3 d, the two bands in the NO^+ region were of comparable intensity (Figure 47c), and after 2 weeks the 2298 cm^{-1} band was the more intense, with the 2230 cm^{-1} band as a shoulder (Figure 47d). On dissolving the evacuated compound in ethyl acetate and reprecipitating with N_2O_4 , the spectrum reverted to that of Figure 47a. These observations led to the conclusion that excess N_2O_4 may be associated in some way with the NO^+ cation in an analogous manner to that known for diethylnitrosamine, in which two molecules of this solvent coordinate to NO^+ ,

Figure 47: Changes in IR spectra of $\text{Fe}(\text{NO}_3)_3 \cdot n\text{N}_2\text{O}_4$ adduct with progressive evacuation. (Reproduced and modified from [394].)

producing a consequent shift in the IR absorption band. This observation supported the theory that the compound $[(\text{N}_2\text{O}_4)_2\text{NO}]^+[\text{Fe}(\text{NO}_3)_4]^-$ or $\text{Fe}(\text{NO}_3)_3 \cdot 3\text{N}_2\text{O}_4$ may be a discrete entity. Later tests supported the assumption that the adduct has the composition $\text{Fe}(\text{NO}_3)_3 \cdot 1.5\text{N}_2\text{O}_4$ [395]. Equilibrium vapor pressures were measured in the system $\text{Fe}(\text{NO}_3)_3 \cdot n\text{N}_2\text{O}_4$ ($n = 1 - 6$) to see at what ratio compound formation might occur. $\text{Fe}(\text{NO}_3)_3 \cdot 1.5\text{N}_2\text{O}_4$ was recognized as a solid phase in equilibrium with N_2O_4 . The presence of traces of HNO_3 in addition to N_2O_4 influences the physical properties

and the chemical behavior of the flow-decay deposit. The adduct was further characterized by Raman spectra, NMR, XRD, magnetic moment measurements, and Mössbauer spectra. The XRD crystal structure of the adduct $\text{Fe}(\text{NO}_3)_3 \cdot 1.5\text{N}_2\text{O}_4$ indicated that it should be represented as $3\text{NO}^+\text{NO}_3^- \cdot 2[\text{Fe}(\text{NO}_3)_4]^-$ [274].

The rates of dissolution of iron from Al-2014, Ti-6Al-4V, and CRES-347 stainless steel by N_2O_4 were measured by immersing radioactive samples of the alloys in N_2O_4 [5]. After immersion of the alloy, the samples were removed and the solutions examined for radioactivity. No iron was detected in the N_2O_4 containing the titanium or aluminum samples. However, radioactivity from some unidentified element was found in the N_2O_4 containing the titanium sample, which indicated that a reaction with the sample had occurred. The reaction rate of N_2O_4 with 347 stainless steel varied directly but not linearly with the sample surface to propellant volume ratio. Iron-free N_2O_4 , prepared by distillation, was stored for approximately 2 months in tanks made from the three sample alloys. Following storage, the N_2O_4 was flowed through a 2- μm stainless steel filter under conditions known to be conducive to flow decay. No decay was found with the N_2O_4 stored in the Al-2014 or CRES-347 stainless steel tanks. About 15% decay occurred with N_2O_4 stored in the Ti-6Al-4V tank. Flow decay resulting from passage of N_2O_4 through 2- μm nominal stainless steel filters was studied as a function of added iron concentration. With new filters, no flow decay occurred when less than 3.6 ppm iron (as iron nitrate) was added to the as-received N_2O_4 . Following successful laboratory experiments with molecular sieves, a larger molecular sieve filter, suitable for field use, was constructed for purifying N_2O_4 . Approximately 90 kg (200 lb_m) of as-received N_2O_4 (containing ~0.5 ppm Fe) was filtered through 0.9 kg (2 lb_m) of Linde type 13X molecular sieves of 100/120 mesh. During the filtration, a sample of that filtrate was withdrawn following each 8.1 kg (18 lb_m) increment of flow. These samples were examined by atomic absorption spectroscopy for iron concentration. No iron was detected in any of the samples since the readings did not exceed the instrumental detection threshold. The propellant-to-filter mass ratio was 1000, and the filtered propellant remained well within the specification limits. Filtration through molecular sieves thus appeared to be a practicable technique to eliminate flow decay as a problem from operational weapon and space systems. Samples of three metal alloys, Al-2014, Ti-6Al-4V, and CRES-347 stainless steel, were immersed in iron-free specification-grade brown N_2O_4 , and the rate of dissolution of iron from the metals was measured as a function of dissolution time, surface-to-volume ratio, state of agitation, and temperature. This was accomplished by activating coupons of these metals in a thermal neutron flux of $3 \times 10^{12} \text{ n cm}^{-2} \text{ s}^{-1}$ for 10 h ($^{58}\text{Fe} + \text{n} = ^{59}\text{Fe}$), immersing the coupons in N_2O_4 , and measuring the level of activity of radioactive Fe in the N_2O_4 after the coupons were removed. From the knowledge of the ratio of radioactive to non-radioactive iron atoms, the iron concentration in parts per million was then calculated.

Two methods of introducing known amounts of iron to the N_2O_4 were used to demonstrate the effectiveness of the purification method: In the first, known amounts

of iron were added to a tank of N_2O_4 in the form of iron(III) nitrate. In the second, iron-free N_2O_4 was stored in Al-2014, Ti-6Al-4V, and CRES-347 stainless steel tanks for an extended period of time, during which the N_2O_4 was allowed to react with the tank walls. One of the objectives of flow testing was to demonstrate elimination of flow decay by subsequently passing the propellant through a molecular sieve filter. This was accomplished by flowing contaminated N_2O_4 that was known to undergo severe flow decay through the molecular sieve filter and then again through the flow system to verify that flow decay no longer occurred. Since severe decay was experienced after the addition of 4 ppm iron, this was the point at which the use of molecular sieve purification appeared appropriate.

One has to assume that any commercially supplied dinitrogen tetroxide will have the potential of causing flow decay, if suitable (that is, adverse) conditions are present during flow. Rocketdyne conducted a number of investigations of various aspects of flow decay, beginning in 1964. An experimental and analytical program was conducted as part of a systematic engineering parametric study to establish the necessary engineering criteria for the prediction and prevention of flow decay in operational nitrogen tetroxide systems [396]. All materials of construction in the flow bench were selected to be compatible with NTO. The tanks, valves, fittings, and fluid lines were made of type 304, 316, 321, or 347 stainless steel. Valve seats and stem packings were made of either Teflon or Kel-F. Teflon tape was used as the thread lubricant on pipe fittings. Tests were done with both green and reddish-brown nitrogen tetroxide over ranges of seven other parameters: initial propellant temperature, temperature drop before reaching the test section, time during which the temperature drop was imposed, filter pore size, local velocity through the filter, total volume per unit filter area of propellant passing through the filter during a test, and iron-saturation condition. Flow decay was observed under some test conditions but was absent under other conditions. The rates of decay ranged up to 2.8%/min, although the mean rate was about 0.5%/min for all tests in which any significant flow decay occurred. It was possible to deduce information about the effects of these eight major independent variables on flow decay. However, it was found that the effects of these parameters were generally not simple or independent of each other; they exhibited many interdependencies. In addition, there were threshold effects for flow decay (i.e., an identifiable boundary between a range of variables for which no flow decay occurred, and a range for which flow decay occurred at varying rates). These thresholds were not sharp, and they further depended upon interactions of the independent variables.

In order to test the suspected volatility of iron compounds that would cause errors in iron analysis results, an authentic sample of nitrosyl iron(III) tetranitrate had to be prepared, which would then be used to dope pure, iron-free NTO to generate known iron concentrations in the oxidizer [302]. The chosen method for preparation of nitrosyl iron(III) tetranitrate was the reaction of iron pentacarbonyl with dinitrogen

tetroxide. The product contained ~19% Fe, while the theoretical iron content should have been 16.7% Fe. See also [397].

The flow-decay problem associated with NTO has become an important factor in the design of small, bipropellant propulsion systems that need to survive decades-long deep space missions such as Galileo at Jupiter or Cassini at Saturn. The objective of a program established at the JPL was to alleviate this problem by **(1)** developing a process to purify NTO to a level of contamination that would minimize the precipitation of iron-contaminated species, and **(2)** establishing component cleaning and passivation procedures that would prevent recontamination of the propellant [398]. While a number of potential methods for purification of nitrogen tetroxide existed, the method employing molecular-sieve column treatment appeared to offer the advantages of simplicity of implementation, relatively low cost, and, at that time, proven capability to operate in the field as well as the laboratory. In general, the molecular-sieve adsorption column treatment of mixed oxides of nitrogen (MON-1 or MON-3) resulted in little change in NO concentration (well within specifications), efficient removal of contaminant iron and other metals, efficient removal of water (HNO_3 and H_2O) when the column was activated, apparent removal of chloride impurity, and no introduction of deleterious material from leaching of the zeolites employed.

A 50-L cylindrical CRES-304L tank and a Ti-6Al-4V tank were filled with freshly distilled MON-1 and stored for 20 and 10 months, respectively, at a constant temperature of 313 K (40 °C) under a helium pad of 5 bar [399]. Because corrosion products are less soluble in MON-1 than in MON-3, this was considered a worst-situation test if later flights would use MON-3. Oxidizer samples were withdrawn from each tank after 1, 3, 6, 10, and 20 months of storage. Prior to sampling, the temperature was reduced to 293 K (20 °C), and the tanks were agitated by shaking. The initially high corrosion rate of CRES decreased after about 1 month. The iron concentration in the oxidizer remained constant at 0.7 ppm for the remainder of the test. The Ti-6Al-4V tank showed little corrosion, and it was mostly aluminum that was leached from the tank walls. No flow decay was encountered when the distilled and stored and off-loaded MON-1 propellant was passed through 10-N rocket thrusters intended for the ESA Olympus mission. However, flow decay in a 20- μm filter was a problem in similar tests with plain military-specification-grade NTO that had been stored in a mild steel tank for 96 months before being transferred to a CRES run tank containing 1.8–2.1 ppm Fe, particularly if the propellant was cooled from 313 K (40 °C) to 268 K (–5 °C) after it had been stored for a long time. It was therefore important to determine the causes of flow decay; find propellant purification, mode of operation, and material selection methods to avoid flow decay; and find recovery methods for an affected system during operational use in space. One method of recovery was to heat the propellant to 333 K (60 °C).

Flow decay depends on the rate of corrosion of stainless steel in contact with NTO and the solubility of iron nitrate and its hydrolysis products in NTO. Galileo was the first bipropellant-powered interplanetary spacecraft to orbit Jupiter, and its active mission duration was much longer than any of its bipropellant-powered predecessors,

which were only lunar orbiters or interplanetary fly-by probes. There was concern that flow decay might hamper the mission after several years in orbit. An effort was made to summarize the state of knowledge about flow-decay problems and their potential impact on the success of the Galileo mission [281]. Existing leaching-rate data were applied to exposed stainless steel surface-to-volume ratios on Galileo, and additional benchtop experiments were started with authentic components immersed in MON. When the launch of Galileo was postponed, the MON that was off-loaded after having spent several months in the tank could have been analyzed to obtain additional leaching-rate data.

The rate of formation of metal nitrates in dinitrogen tetroxide was fed into a computer model to predict the saturation point of metal nitrates in N_2O_4 [400]. Means of reaching the saturation point were examined, and a relationship was established for the reaction/formation rate and diffusion rate of metal nitrates in N_2O_4 .

6.4 Metallic Materials for Dinitrogen Tetroxide Service

The selection of metallic materials of construction for wetted use with N_2O_4 is simple compared with similar tasks for the various forms of nitric acid [401, 402]. Dinitrogen tetroxide and MON are less aggressive corrodents than nitric acid, but one must remember that it takes only a small amount of moisture for all the problems earlier encountered with nitric acid to resurface.

The corrosive effects of dinitrogen tetroxide on mild steel, aluminum, stainless steels, and titanium were determined quantitatively under static and dynamic flow conditions at six water concentrations up to 3.2 mass-% H_2O and four temperatures up to 343 K (74 °C) [403]. The corrosion of carbon steel (ASTM A-285 grade C) and Al-5086 was less than 0.5 mils per year in nitrogen tetroxide containing up to 0.21 mass-% water at 343 K, increasing to 50 mils per year at 3.2 mass-% water and 343 K. Negligible corrosion was observed under severe conditions with CRES-304L, titanium 75A, and Ti-6Al-4V, whereas high stress-corrosion cracking was observed in tests of carbon steel, high-strength steel, and aluminum in nitrogen tetroxide containing 0.1 mass-% water and 1.6 mass-% water at 343 K. Significant corrosion of CRES-304L occurred in the presence of Teflon. Dynamic tests showed no significant corrosion of CRES-304L or PH15-7Mo stainless steels, and average rates were seen of 0.05 mils per year for aluminum and 0.33 mils per year for carbon steel after 205 h of exposure to commercial dinitrogen tetroxide flowing at a velocity of 3 m/s (10 ft/s) at 303 K (30 °C).

The corrosion rates of carbon steel, stainless steel (304L and PH 15-7 Mo), aluminum (Al-5086), and titanium (75A and Ti-6Al-4V) in dry and wet nitrogen tetroxide were determined under static conditions of exposure at 264–347 K (–9 to 74 °C) [344]. Carbon steel and aluminum were attacked in proportion to water concentration and temperature. Stainless steel 304-L and titanium were not attacked, and PH 15-7 Mo was

only slightly attacked. Significant corrosion of stainless steel (CRES-304L) occurred in the presence of Teflon. Corrosion by dry nitrogen tetroxide under flow conditions was negligible. Teflon was the most resistant of the plastics exposed to nitrogen tetroxide.

When a wide range of different metals were tested for compatibility with N_2O_4 at 316.5 K (110 °F) for periods of 1.5–3 years, it was found that the least corroded metals were titanium alloys [404], iron alloys, cobalt alloys, some nickel alloys, and tantalum [405]. Molybdenum, magnesium, and some aluminum and nickel alloys were not compatible. The exposed metal samples were examined for weight loss, appearance of the corroded surface under the light microscope, and XRD of the corrosion products. The propellant used in the compatibility studies was analyzed for water by a gas chromatographic method, for nitric oxide by a spectrophotometric method, and for chloride by a wet chemical method.

Russia and its predecessor the USSR have launched thousands of rockets with N_2O_4 as the oxidizer, and, accordingly, they have amassed a substantial amount of experience in materials selection for N_2O_4 service. However, only very little of that literature has found its way into Western library collections [406].

Dinitrogen tetroxide corrosion phenomena and proposed mechanisms of corrosion with various metals, mostly stainless steels, are well described in [407].

Cryopanel in a vacuum space simulation chamber are periodically cycled between 77 and 300 K, and if the engine is operated oxidizer-rich during startup, N_2O_4 condensate on the panels melts and drips off after completion of a rocket test under simulated vacuum conditions. A black epoxy coating of CRES-304 panels suffered no apparent damage in one series of short tests, but pit formation in the coating, pitting beneath the coating, and intergranular corrosion in weld areas was detected in tests with longer exposure durations [408]. An epoxy-coated CRES-304L sample suffered microscopic cracking and blistering of the coating and surface pitting beneath the coating. In one worst-case test in which the N_2O_4 partial pressure in the chamber was 0.5 kPa (4 mm Hg), Al-1100, phosphorus-deoxidized copper, and stainless steel panels were exposed to vapor and condensate while subjected to external bending stresses similar to those from thermal differential expansion [409]. None of the panels cracked.

The JPL has done extensive materials compatibility testing with NTO, MON, and other rocket propellants, and some of the testing was extended for close to 20 years [410]. Interim status reports were published at 5-year intervals. The scope of the testing was to provide data necessary for the design of interplanetary spacecraft on long-term missions. The testing was done in “real time” at a constant temperature of 316 K (110 °F). Materials were tested in unstressed and stressed conditions and partially submerged conditions, such that there were liquid-exposed and vapor-exposed areas on each coupon. Groups of materials were tested in (1) bimetal separated, (2) bimetal contact, (3) welded, (4) brazed, (5) plated, and (6) coated configurations. Most of the materials originally placed into testing were identical to materials typically used in the Mars Viking Orbiter propulsion subsystem. The coupons were sealed in borosilicate (Pyrex) glass ampoules. Strain gauges attached

to the outside of the ampoules were supposed to allow inside pressure measurement, but the bond of the strain gauges to the glass failed, and pressure readings could not be obtained [411]. At the ten-year milestone, 38 samples removed indicated that most materials tested, with the exception of nickel, were compatible with MON-1 [412, 413]. On Al-6061-T6 the primary effects were corrosion and formation of a surface film; the oxide layer of the surface film may flake off and cause particulate contamination and clogging. In all CRES alloys (302, 303, 304L, 316, 321, 347, 17-4PH, and 17-7PH), only minor corrosion was seen. The amount of iron dissolved from the surface varied, with the most iron found in propellant off-loaded from 17-4PH and from a welded CRES-304L coupon. Titanium alloy samples had a substantial weight loss.

While most materials compatibility testing has been done under static, stagnant conditions, this is not what metals are exposed to in feed systems or rocket engines during operation of the rocket engine. More sophisticated corrosion testing of metals in flowing NTO exposed the specimens to more severe conditions than under static tests. As a consequence of the cavitation and turbulence on the surface, material corrosion may be accelerated due to the removal of passivating layers. One must be cautious when applying static corrosion-rate data to a dynamic environment.

A thorough and comprehensive summary of materials compatibility data of metals and non-metallic materials is contained in a NASA WSTF report that was later reissued as an AIAA Special Report [209]. It included a description of the criteria for rating metal degradation in NTO used by various investigators. In reviewing the literature on materials compatibility with NTO (and other propellants), one quickly realizes that the various investigators used different criteria to establish the compatibility ratings. Several materials NTO compatibility tables were compiled based on published data from four literature sources. This also included lists of materials that were found to be incompatible and must be avoided.

6.4.1 Compatibility of Ferrous Steels with Dinitrogen Tetroxide

One of the landmark studies investigated the corrosion of several pure metals and alloys in stagnant and flowing NTO containing six different levels of moisture up to 3.2 mass-% H_2O and at four different temperatures between 264 and 347 K (–9 to 74 °C) [403]. For example, a steel (ASTM A285-C) suffered in stagnant N_2O_4 with 0.2% H_2O at 347 K (74 °C) only a slow rate of corrosion (0.5 mm/a) (mm/a = millimeter/year), but at the upper range of the water content, at 3.2% H_2O , the rate of corrosion was several orders of magnitude faster, namely 50 mm/a. Comparing rates of corrosion in stagnant and flowing (3 m/s) N_2O_4 containing 0.20% H_2O at 303 K (30 °C), it was observed that the sample in flowing N_2O_4 corroded at only a moderately faster rate (0.33 mm/a) than quiescent N_2O_4 .

Precipitation-hardened PH-15-7-Mo steel suffered little attack, whereas CRES-304L was hardly attacked at all, and it still constitutes the material of choice for most tanks and conduits.

There have been sporadic reports that N_2O_4 in the presence of Teflon caused increased corrosion of stainless steel, but the cause for this observation has not been identified.

MS steel fittings for use in diesel fuel and hydraulic systems are often plated with cadmium to prevent rusting. Cadmium plating does not offer any protection for service with N_2O_4 because the coating will rapidly corrode and peel off. Protecting the cadmium by a coating of polyethylene may help to protect against NO_2 vapors but will not help much if liquid N_2O_4 leaks out.

Stainless steels of the types AISI-300, AISI-400, AM-350, AM-355, 17-4-PH, and 17-7-PH or alloys Superalloy A-286 and Haynes 16-25-6 can also be used for N_2O_4 service [66, 414].

An examination of the corrosion of Ch18N10T (18/10Ti) steel in dinitrogen tetroxide at high temperature and high pressure under radiation conditions in a nuclear reactor showed that the radiation had no aggravating effect on the corrosion of this steel under these extreme conditions [415].

Whereas in the beginning of the use of NTO and MON as rocket propellants the storage duration requirements were only of the order of a few years, later developments required safe storage for ten or more years. It became difficult to select stainless steels that would meet the long-term storage requirements without contamination of the propellant by leached corrosion products and with maintenance of the mechanical integrity of the tanks [416].

In addition to conventional metallurgical corrosion investigation techniques (mount, cut, polish, etch), electron-beam analysis and imaging techniques have been used to study the surface of cryoformed CRES-301 stainless steel samples before and after passivation and before and after immersion in MON-3 [417–419]. Electron-beam methods that can be used for surface analysis are electron microprobe, ESCA-XPS, SEM-EDAX, and Auger spectroscopy. In one case, it was demonstrated that an initial electrochemical attack on the metal by the propellant was retarded by the development of a protective film on the metal, accompanied by minor adulteration of the propellant. In clean propellant, there was no indication of pitting or intergranular corrosion.

CRES-301 and CRES-304L have been widely accepted as the material of choice for surface-tension screens in propellant management devices in tanks in zero-gravity operation or for the tank wall and pressure shell itself [420]. The surface has to be carefully cleaned and passivated for such applications, in particular satellites and planetary space probes with mission durations of 12–15 years and more. See also [421].

The resistance of steel 09Kh16N15M3B and alloy 65Cr31Fe3Al0.3Zr against corrosion by dinitrogen tetroxide can be improved by enriching the surface with chromium [422]. This can be achieved by treatment with water steam at 1120–1170 K, followed by reduction under hydrogen, which forms a chromium layer ~2 nm thick. Samples exposed to NTO under pressure at 420 K and 16 MPa for 2000 h were practically unchanged, whereas an untreated control sample was badly corroded.

The mass loss of the treated sample was 20 times less than that of the untreated sample.

The interaction of nitrogen tetroxide oxidizer (in the form of NTO or MON) with stainless steel (CRES) has been studied for a long time. In an effort to extend the CRES/NTO corrosion database, based on earlier assessments made prior to the launch of ESA's Olympus satellite and NASA's Galileo space probe in the 1980s, an extensive parametric study of CRES/NTO corrosion was conducted, intended to provide a reliable and comprehensive database to support future spacecraft design and operation [423]. Data were obtained showing the effects of propellant composition (H_2O , NO, Cl), steel specification, temperature, surface-to-volume ratio, and surface passivation processes on corrosion rates. It was found that the long-term (up to 250 d) corrosion rate of 304L stainless steel is

- strongly related to the water content (MON-1 containing 0.15% H_2O was ten times more corrosive than the same oxidizer with 0.01% H_2O)
- in MON-3 half of that in MON-1
- lowest for electropolished sheet material, which is five times less than non-passivated material (nitric acid passivation or pickling in nitric/hydrofluoric acid, followed by nitric acid passivation, gave intermediate corrosion resistance)
- doubled by raising the temperature from 278 to 308 K (41 to 95 °F)

Factors that did not significantly affect the corrosion rate, or were within experimental error, were the initial chloride or iron content. Effects of the alloy type (301, 304L, or 321) were overshadowed by surface treatment/passivation effects. The surface-to-volume ratio affected the concentration of dissolved iron but not the rate of corrosion.

Deposition of iron-containing corrosion products, mostly an iron(III) nitrate-dinitrogen tetroxide adduct, occurs after the solubility limit of the contaminant has been exceeded, and it has been the cause of numerous in-flight problems with spacecraft. In the absence of convection and agitation, the rate of diffusion of iron ions through dinitrogen tetroxide, a known electrolyte, has not been totally investigated. If it effectively diffused, then it would be less likely to precipitate near its formation area on the surface of steel. Precipitation of iron-nitrate adduct material occurs after iron saturation in the oxidizer, which is therefore a function of the solubility of iron, the initial iron concentration in the oxidizer, and the rate of diffusion of iron through the oxidizer. The precipitate structure has noted variability that appears to be based on the water content of the oxidizer. Low-water-content oxidizer yields a crystalline adduct, whereas higher-water-content oxidizer yields a sticky solid or a viscous insoluble gel, the cause of flow decay. Some mission planners have resorted to periodically flushing NTO that was stagnant in lines, filters, and valves by firing the thrusters even if there is no need to do any active propulsion for momentum wheel desaturation or orbit adjustment. Periodic flushing avoids the buildup and precipitation of iron compounds from corroded parts in the system. Calculations suggested that systems should be fired or flushed fairly often initially in order to prevent iron nitrate corrosion product from

harming the system. After 200 d of exposure, the amount of time between firings can be increased considerably. The power law data fit suggested that after around 3 years of on-orbit operation, thrusters need not be fired or flushed for another 3 years [424].

Some investigators claimed that the corrosion occurs only within the first 30 d and then stops. This conclusion was based on very limited data, namely two points at two test conditions.

6.4.2 Compatibility of Aluminum Alloys with Dinitrogen Tetroxide

While aluminum alloys as a structural material for NTO or MON tanks may be more economical than titanium alloy tanks and less susceptible to corrosion product leaching and flow decay than steel tanks, there is concern that the oxide coating that develops may flake off and that the aluminum oxide particles may clog filters.

Microscopic leaks of N_2O_4 through capillary cracks, pores, or microporosity under the earth's surface or underground storage conditions in a moist atmosphere would not be so disastrous if the chemical did not form nitric acid at the leak site and rapidly increase the size of the leakage path through crevice corrosion [425, 426]. Indicator paints have been developed that change color and provide an early visual warning where a microscopic leak has occurred. Residual cleaning agents or propellant may get trapped in narrow passages in propellant tanks and are difficult to remove. The mechanisms by which crevice corrosion can occur in a narrow passage of Al-2014 aluminum were studied both experimentally and theoretically for exposure to **(1)** water and fuel (a mixture of hydrazine and UDMH), and **(2)** water and oxidizer (dinitrogen tetroxide). With each of these two reacting systems, one may form two displacement systems. In one case it was assumed that the capillary was initially filled with water, which was later displaced by propellant. In the other case the capillary was initially filled with propellant, which was later displaced by water. The crevices of small diameter were open at one end to a propellant tank but were closed (dead-ended) at the other end. This included weld cracks or weld porosity.

Small containers made from Al-2014 and Al-6061 were subjected to short-term compatibility tests with N_2O_4 to determine the effect of different cleaning methods [427]. In other samples that were exposed for 46 months, only minor differences were noted in the pre-exposure and post-exposure appearance of the metal surfaces.

Aluminum 5086 corrodes in N_2O_4 with less than 0.2% H_2O at 347 K (74 °C) only very slowly (0.5 mm/a). Even in flowing N_2O_4 at 303 K (30 °C), the rate of corrosion is only 0.05 mm/a [403]. The rate of corrosion of aluminum is proportional to the water content of N_2O_4 and the immersion test temperature, similar to the behavior of stainless steels.

Aluminum alloys 1100, 5052, 6061, 6066, 356, B 356, and Tens 50 are suitable materials of construction [66, 428]. However, Al-2024 is not suitable for N_2O_4 service. Al-2219 can be used for pressurized tanks [429]. TIG-welded areas of Al-2219 are especially susceptible to corrosion in NTO [430]. Corrosion experiments of a TIG-welded

aluminum alloy structure were conducted under both mild and accelerated corrosion conditions by changing the water content in N_2O_4 . The experimental results indicated that both general and accelerated corrosion processes of the TIG-welded structure of aluminum alloy 2219 in N_2O_4 followed a linear equation for its time dependence, and the corrosion products were unchanged regardless of the water content in the N_2O_4 solution.

Pure aluminum has good resistance to dry N_2O_4 , but it is too soft and not strong enough for many applications. Aluminum alloys better suitable for N_2O_4 service are Al-3003 and Al-5052. There are some contradictory reports in the literature about the suitability of Al-6061 and Al-2024.

Aluminum Al-2024-T6 is compatible with dinitrogen tetroxide (N_2O_4 MIL-P-265398). However, experience has shown that N_2O_4 leakage can occur with this Al-2024-T6 material, usually in the heat-affected weld zone, in a humid environment (30% R.H.) [431]. It was observed that if the relative humidity was of the order of 30% or lower, the nitrogen dioxide vapor from a leak dissipated into the atmosphere and did nothing to aggravate the leakage. If the relative humidity was of the order of 40% or greater, however, it did not dissipate, but rather hydrolyzed, forming dilute nitric acid on the exterior surface in the immediate vicinity of the leak and causing attack from both sides of the tank wall. During the same tank storage program, Bullpup Al-2024-T6 tanks initially intended for IRFNA and MAF-2 were later tested with NTO with good results.

The corrosion rates of aluminum alloys in dry NTO are an order of magnitude higher than those of stainless steels. As with stainless steel, and contrary to the trend observed for titanium, the corrosion is worse when more water is present. With time, aluminum ions enter the MON and form adducts whose composition is similar to those of the iron nitrate adducts. Thick oxide films form on aluminum, but they are not necessarily protective because they tend to spall, contaminating the propellant with insoluble oxide. A dubious method to protect aluminum alloys would be to pair them with iron alloys. Iron would act as a sacrificial anode; iron goes into solution (potentially precipitating and causing flow decay), but the solution process is quickly arrested by the formation of a protective film on the steel.

Aluminum cylinders containing 4 L of NTO and made of Al-2024-T6 or Al-6061-T6 were used during a 2-month storage test [427]. Various anodizing treatments have been evaluated to make aluminum more compatible with NTO and MON. Soft aluminum gaskets (Voishan seals) are often used to obtain tight connections between steel-steel AN fittings, but they cannot be used with NTO because they deteriorate within a few days.

Aluminum alloy LD10 double-cantilever beam specimens were corroded under the conditions of UDMH, N_2O_4 , or 3.5% NaCl aqueous solution immersion [432]. The stress-corrosion crack propagation behavior of this aluminum alloy in N_2O_4 was relatively slight.

6.4.3 Compatibility of Titanium Alloys with Dinitrogen Tetroxide

The combination of high strength-to-weight ratio, excellent mechanical properties, and corrosion resistance makes titanium a material choice for many applications in corrosive environments and as structural materials. In most cases, titanium alloys are superior to aluminum alloys for applications where the material is in contact with N_2O_4 . Titanium tank half-shells are formed by spinning or explosive forming and are then welded at the girth, often including a surface-tension screen as a propellant management device for zero-gravity propellant expulsion. Because titanium wire and titanium screens are not always available, the surface-tension screens are usually made from stainless steel, setting up the potential for galvanic corrosion between dissimilar metals in electrical contact with each other. Pure, non-alloyed titanium parts that have minimum titanium contents ranging from about 98.6, to 99.5 mass-% are used primarily for corrosion resistance, but pure titanium is soft and not very strong. The most widely used titanium alloy is the Ti-6Al-4V α - β phase alloy [404, 433].

Typical red N_2O_4 attacks unstressed Ti-6Al-4V to a small but measurable degree at 345–347 K (72–74 °C), i.e., 0.8–0.9 mils/year. At room temperature the rate of attack is negligible, i.e., 0.06 mils/year. MON-0.4 and MON-0.8 showed no evidence of corrosive attack at 345–347 K (72–74 °C), i.e., 0.06 mils/year. One mil is one-thousandths of an inch.

Titanium Ti-75-A and Ti-6Al-4V were tested under similar conditions as the steel discussed above [403]. Neither of the two alloys suffered any corrosive attack, not even in very moist (3.2% H_2O) N_2O_4 and not even at the maximum temperature tested (347 K [74 °C]). This corrosion resistance is a substantial advantage of titanium alloys over aluminum alloys.

For several decades, materials scientists were so preoccupied with the problem of stress corrosion cracking with NTO in titanium alloys that reliable conventional corrosion data were hard to obtain.

In a storage test with 57-L tanks at the Air Force Rocket Propulsion Laboratory (AFRPL), all of the titanium tanks leaked within less than 35 d after loading with N_2O_4 [431]. Both the Ti-6Al-4V and the Ti-5Al-2.5 titanium alloys in the annealed condition leaked. At the beginning of the test program, consideration was given to the use of the NASA-grade N_2O_4 (MSC-PPC-2A specification [green]) in the loading of the titanium tanks because of the stress-corrosion problem encountered with MIL-P-26539B specification N_2O_4 (brown). The stress levels in the tankage, based on nominal loads and thickness, however, were considerably below the threshold for stress-corrosion cracking reported (16 versus 90 ksi). The test temperature was to be significantly below the temperatures at which problems were encountered (302.6 versus 316.5 K [85 versus 110 °F]). On the basis of these two considerations, stress corrosion was not thought to be significant, and the tanks were loaded with MIL-P-26539B specification N_2O_4 (brown). Fracture analysis of two of the five leaks revealed that stress-corrosion cracking was present in the failure area and was very probably responsible for the leaks. It is quite likely that warping loads that were

introduced by welding in the leak area resulted in residual stresses that significantly increased the local stress level above the calculated general-membrane stress level.

After the MON was off-loaded from Galileo due to a launch delay and the tank purged with dry nitrogen (it could not be evacuated), it was to be expected that a thin film of less volatile nitric acid would remain behind and might cause corrosion during the idle period of storage. In tests of the fracture toughness and stress-corrosion threshold of identical Ti-6Al-4V samples exposed to nitric acid, it was found that the tank's structural integrity was not degraded by nitric acid exposure [434].

Previous (prior to 1994) studies of corrosion of Ti-6Al-4V in NTO indicated that the corrosion of Ti-6Al-4V in NTO is uniform, "a light etching without pitting," although the Ti:Al ratio on the surface varied depending on the water and chloride content of the oxidizer.

Two corrosion products, $\text{TiO}(\text{NO}_3)_2$ and $\text{Ti}(\text{NO}_3)_4$, not typically found on the surface, are stable in contact with NTO [367]. Both are white solids that are readily hydrolyzed by traces of water. The tetranitrate $\text{Ti}(\text{NO}_3)_4$ is very volatile. The titanyl nitrate and its NTO solvate $\text{TiO}(\text{NO}_3)_2 \cdot \text{N}_2\text{O}_4$ are less well characterized and would probably decompose to TiO_2 when heated.

Earlier attempts to quantify the rate of corrosion of Ti-6Al-4V in NTO or MON yielded ambiguous results because the mass losses of the coupons were too small to be measured, and the analytical methods to analyze dissolved corrosion products were not sensitive enough [367]. The investigators had to increase the surface-to-volume ratio to 6 cm^{-1} to obtain measurable quantities of corrosion products.

The concentration of leached metals was measured in off-loaded oxidizer after exposing Ti-6Al-4V coupons at a surface-to-volume ratio of 6 cm^{-1} at 303 K (30 °C) for up to 552 d to NTO or MON-3 with several different water contents [435, 436]. The results are summarized in Tables 43 and 44. Table 43 gives the concentration of dissolved metals, and Table 44 gives the corrosion rates derived from these numbers. The results showed that the corrosion of Ti-6Al-4V in both oxidizers proceeds to a limited extent and then stops. At 303 K and a surface-to-volume ratio of 6 cm^{-1} , the oxidation of the surface appeared to be complete within 55 d for NTO and 41 d for MON-3. The extent

Table 43: Leached metal amount from Ti-6Al-4V immersed in NTO or MON-3.

Oxidizer	Water content, mass-% H_2O equivalent	Duration, d	Total quantity of metal dissolved, ppm		
			Ti	Al	V
NTO	0.003	552	3.5 ± 0.5	0.43 ± 0.01	0.59 ± 0.02
NTO	0.02	55	6.95 ± 0.30	0.32 ± 0.01	0.85 ± 0.14
MON-3	0.01	49	0.21 ± 0.03	—	0.017 ± 0.003
MON-3	0.02	41	0.18 ± 0.01	—	0.016 ± 0.001
MON-3	0.15	43	0.25 ± 0.01	—	0.016 ± 0.001

Data source: [435]

Table 44: Time-averaged corrosion rates of Ti-6Al-4V immersed in NTO or MON-3 at 303 K.

Oxidizer	Water content, mass-% H ₂ O equivalent	Duration, d	Corrosion rate, mils/yr × 10 ⁶		
			Ti	Al	V
NTO	0.003	552	45*	95*	205*
NTO	0.02	55	1060	813	3230
MON-3	0.01	49	42	51	73
MON-3	0.02	41	36	98	67
MON-3	0.15	43	47	—	90

*Corrosion probably leveled off before vessel was opened after 552 d

Data source: [435]

Note: mil = 1/1000 inch

of MON-3 corrosion appeared to be unaffected by the water content in the range of 0.01–0.15 mass-% H₂O equivalent.

Dry (0.003 and 0.2 mass-% water equivalent) NTO is the more corrosive medium toward both alloys. The iron oxidation product dissolves more readily in MON-3, whereas the titanium alloy corrosion products are more soluble in the N₂O₃-free medium. In NTO, the oxidation penetrates to a depth of 30–40 Å.

For a long time there has been quite a concern that the impact of hypervelocity projectiles (meteorites) on N₂O₄-filled titanium tanks might cause an explosive combustion, but this situation would lead to system loss in either case, whether it is accompanied by a fire or not (Section 6.4.6). Initially the concern was so large that at one time titanium was not recommended to be used with N₂O₄. Hypervelocity impact tests with N₂O₄ in titanium, aluminum, steel, or fiberglass-reinforced plastic tanks did not result in explosions, whereas titanium tanks filled with liquid oxygen combusted with a fireball [437]. Titanium tubes filled with N₂O₄ and externally impacted with the bullet of a .30-06 cartridge showed evidence of burning over an area of about 1 inch from the point of impact.

The impact sensitivity of commercially pure titanium, Ti-6Al-4V, and precipitation-hardened 15-7 Mo stainless steel in liquid NTO was measured under a range of stimuli, including shearing, scraping, galling, impact by massive strikers, and high-velocity bullets [438]. See also [439–442].

Freshly exposed titanium surfaces at the point of tensile rupture may react spontaneously with NTO and ignite [443].

6.4.3.1 Stress-Corrosion Cracking of Titanium Alloys in Dinitrogen Tetroxide

Although dinitrogen tetroxide is less corrosive than RFNA, the potential for stress corrosion still exists and requires careful selection of materials of construction, clean manufacturing methods, and high-purity propellants [354].

The first reported indication of stress-corrosion failure came in early 1965 when a pressurized Ti-6Al-4V (solution-treated and aged) tank filled with liquid N₂O₄

ruptured at Bell Aerosystems Company. Failure came after 40 h of exposure at 314 K (105 °F) and a stress level of 620 MN/m² (90000 psi). Microscopic examination of the tank disclosed a considerable number of cracks that had formed in all areas where the stress level was above 276 MN/m² (40000 psi) [444]. Stress-corrosion cracking will usually occur in N₂O₄ when no significant or measurable amounts of NO (acting as an inhibitor) are present. In the absence of stress, titanium shows almost no corrosion in liquid or gaseous N₂O₄ in tests to 347 K (165 °F).

Another failure in late 1966 of a titanium-alloy tank by methanol-induced stress-corrosion cracking resulted in a flurry of activity to investigate the behavior of titanium and its alloys in various media such as the alcohols and fluorinated hydrocarbons. This particular tank that failed was being pressure tested with dry, reagent-grade methanol, which was used as a substitute fluid in place of the propellant that is intended for ultimate use. During the testing, which was a sustained-pressure test, it was noted that a leak developed in the heat-affected zone of the lower weld. A second tank failed catastrophically, also with methanol as a pressurized fluid. Failures of pressurized tanks occurred in as little as 3 h. Adding 1% water to the dry methanol inhibited the attack. The US Defense Metals Information Center sponsored a seminar on this subject in cooperation with NASA Manned Spaceflight Center. The seminar on "Accelerated Crack Propagation of Titanium by Methanol, Halogenated Hydrocarbons, and Other Solutions," was held at Battelle Memorial Institute in Columbus, Ohio, in March 1967 [445]. This was attended by 139 persons representing 78 individual companies and offices of the US government.

Concern about the potential fracture of Ti-6Al-4V tanks in dinitrogen tetroxide arose already before the spectacular failures in late 1966 of large tanks intended for the Apollo program. Smaller tanks intended for the Lunar Orbiter were examined for critical flaw sizes required for tank fracture, likeliness of small initial flaws to grow to critical size. It was determined if any necessary changes to operating stress levels, proof test or possible substitution with other tank materials would be required to assure mission success [446, 447].

The N₂O₄ stress-corrosion resistance of standard Ti-6Al-4V and extra-low interstitial Ti-6Al-4V alloy coupons with three different heat treatments was measured with specimens stressed 586 to 896 MN/m² (85–130 ksi) and heated to 314 K (105 °F) or 344 K (160 °F) until failure occurred or for a maximum of 30 d [448]. The heat treatments were the conventional solution-anneal-and-age treatment and two duplex treatments which included controlled-rate cooling from above the beta transition temperature followed by the conventional treatment.

Plane-strain cyclic and sustained load flaw growth characteristics were investigated for Ti-6Al-4V forgings and heat affected zones in weldments exposed to N₂O₄ inhibited with 0.49% NO Aerozine-50, MMH, NTO, methanol, Freon-MF, and distilled water (with and without sodium chromate additions) at 291 to 316 K (65 to 110 °F) [447]. Basis for evaluation was the determination of the threshold stress intensity values (that value below which sustained load flaw growth could not occur) in the various liq-

uid environments. The results showed that sustained load threshold values (in terms of initial-to-critical stress intensity ratios) were relatively high, exceeding 75%, with the exception of three environments: methanol, Freon-MF, and at test temperatures exceeding 302K (85°F), also dinitrogen tetroxide. Little or no difference in sustained load behavior was observed between base metal and weld HAZ except in the environment of Freon-MF. In this case, the flaw growth was significantly more pronounced in the HAZ than in base metal. At stress intensity levels below the sustained load threshold value, cyclic load flaw growth rates were quite low, and were not considered to be a serious problem. For the case of methanol, the base metal threshold value was 24% of the critical stress intensity. With regard to the failed Apollo SPS fuel tanks, this value indicated that initial flaws as small as about 0.003 in. deep could have grown to failure when exposed to methanol at maximum operating stress.

Traces of residual methanol and fluorocarbon cleaning solvents were suspected of causing tank ruptures when tanks were later filled with NTO [449, 450]. Subsequent to the stress-corrosion failure of several tanks and a nationwide campaign of coupon testing in the laboratory under carefully controlled conditions, it was noted that highly purified N_2O_4 still caused stress corrosion, but N_2O_4 contaminated (deliberately or not intentionally) by a little NO ("green NTO") did not. This was the discovery of the stress-corrosion inhibiting quality of NO and the beginning of routine use of MON instead of pure NTO. In addition to chemical inhibition, it was also found that glass-bead peening, which introduced residual compressive stresses, alleviated the stress-corrosion problem.

The appearance of tarnish on fracture surfaces, obtained on Ti-5Al-2.5Sn alloy in NTO, seemed to indicate that some similarities exist between tarnish which forms on α -brass in certain ammoniacal solutions and that found on titanium alloys failed in dinitrogen tetroxide [451]. It was suggested that tarnish-rupture mechanism first described brass-ammonia systems also may be involved in failure of titanium alloys in dinitrogen tetroxide.

In tests with a total of 464 titanium alloy specimens in N_2O_4 , 84 failed during the tests [452]. These specimens were tested at either room temperature or 347K (165°F) and at imposed stress levels of 206–930 MN/m² (30–135 ksi). These included 11 unnotched sustained-load type specimens, 20 notched sustained-load type, and 133 bend-test samples. The nitrogen tetroxide used was from a bulk storage cylinder, which came directly from the manufacturer and conformed to the MIL-P-26539A grade. To this grade of N_2O_4 were added various additives and/or contaminants. Some tests used a grade of N_2O_4 which had come to be known as NASA Spec-Grade NSC-PPD-2 and which contained an excess of NO. The Ti-6Al-4V material used was in the STA condition. Some of this was material salvaged from the original failed Apollo tanks while additional samples were prepared from newly purchased and heat-treated sheet. The parameters evaluated in the N_2O_4 test program included many variables of the manufacturing processes including cleaning prior to welding and/or heat treatment, bimetallic couples, various contaminants and inhibitors in

the N_2O_4 , effects of oxidation and heat-treating oxide scale, and anodizing and/or shot peening treatments on the surface of the Ti-6Al-4V tanks. In tests with methanol, of 236 tests completed, 163 of the coupons failed at stress levels of 204–862 MN/m² (30–125 ksi). The time to failure ranged from as little as 2½ h to a maximum of 15 d.

The stress-corrosion cracking (SCC) of Ti-6Al-4V in N_2O_4 was investigated using small coupons in the laboratory as well as full-size flight-weight tanks at 290–345 K (65–165 °F) and stress levels from 170 to 690 MN/m² (25–100 ksi) to determine the time elapsed to start of crack initiation [453]. Cracks initiated at all stress levels at about the same time. An excellent correlation was achieved between crack initiation on laboratory specimens and failure time of tanks. Tests were also conducted on specimens that had been treated with the intent to prevent or delay stress-corrosion attack. Organic and metallic coatings turned out to be unsatisfactory because of insufficient adherence or NTO permeation. Peening with glass beads introduced residual compressive stresses and delayed or prevented stress-corrosion cracking. The prevention of stress-corrosion cracking by adding 0.78 mass-% NO to the N_2O_4 was also substantiated in tests at 345 K (165 °F) extended for 170 h.

In a series of tests, aimed at establishing the chemical composition of reactive and non-reactive N_2O_4 , all 30 U-bend coupons of Ti-6Al-4V cracked during exposure to “red reactive” N_2O_4 , while no cracking was observed in 10 identical specimens exposed to “green” N_2O_4 containing 0.8% NO [19, 454–457]. The results were obtained in four separate tests with 10 specimens each at 348 K (167 °F) for 72 h. Twenty specimens with a radius of five times the thickness broke in half during exposure to red N_2O_4 at a stress level about 90% of the transverse or longitudinal yield strength. Another group of 5 pairs exposed to red N_2O_4 at stress levels of 30, 50, 70, 90 or 100% of the longitudinal yield strength cracked in less than 72 h. Some cracks developed within 24 h at 347 K (74 °C). Dehydrated N_2O_4 required more NO (500 ppm) than normal N_2O_4 (150–200 ppm) to inhibit SCC. The data showed that a cracking N_2O_4 system contained N_2O_4 , NO_2 , HNO_3 , and usually some dissolved O_2 . Non-cracking N_2O_4 contained N_2O_4 , NO_2 , N_2O_3 , HNO_3 , HNO_2 , and H_2O . Addition of O_2 to a reactive N_2O_4 system increased the rate and/or the extent of cracking but not in direct proportion to the O_2 concentration. However, the absence of dissolved O_2 did not prevent SCC. Normally, one would expect that addition of HNO_3 to N_2O_4 would aggravate corrosion problems, but the opposite was true for SCC. Normal red N_2O_4 contains 0.5–0.6 mass-% HNO_3 . Addition of anhydrous HNO_3 to increase the concentration to 1 and 2% caused significant inhibition of SCC at 313 K (40 °C). At 1% HNO_3 , crack density was greatly reduced; at the 2% HNO_3 level, no cracking occurred within 70 h. SCC could not be induced in stressed U-bend specimens by vapor phase contact with mixtures of NO_2 and O_2 at 347 K (74 °C). The N_2O_4 samples were analyzed for the following:

- (1) combined nitric oxide (visible spectrophotometry)
- (2) total protons (NMR)
- (3) distribution of protonated species (near-infrared spectrophotometry)
- (4) dissolved oxygen (gas chromatography)

- (5) combined chlorine (X-ray fluorescence)
- (6) metallic impurities (atomic absorption)

Titanium alloys are susceptible to SCC, not only in NTO but also in hot salt water environments. Methanol, which may have been used as a cleaning fluid, can also induce SCC in titanium alloys [458].

Stress-corrosion susceptibility of Ti-6Al-4V in a variety of fluids was examined after the unexpected failure of a Ti-6Al-4V tank following exposure to methanol and N_2O_4 [459]. Ti-6Al-4V is susceptible to SCC in absolute methanol in both the annealed and solution-treated-and-aged (STA) conditions. The threshold for the annealed alloy appears to be near 50 percent of the yield strength or approximately 482MN/m^2 (70 ksi), while the threshold for STA treated alloy is somewhat less. Long-term exposure tests of Ti-6Al-4V for 2yr to acetone, Aerozine-50, distilled water, absolute ethanol, Freon[®]-PCA, Freon[®]-MF, hydraulic oil, absolute isopropanol, methylhydrazine, kerosene RP-1 or trichloroethylene showed that Ti-6Al-4V is not susceptible to SCC in those fluids.

The stress-corrosion cracking behavior of titanium and Ti-6Al-4V alloy in liquid N_2O_4 has been investigated from a standpoint of thermodynamic considerations and supported by autoradiographic, chemical, and electrochemical potential studies [460]. A hydrogen embrittlement mechanism involving HNO_3 in the commercial N_2O_4 appeared improbable. Another electrochemical mechanism in which O_2 plays a major role has also been proposed.

The compatibility of four maraging high-toughness, low-strength steels (T-1, HY-140, HP-9-4-20, and 18Ni200) with N_2O_4 and UDMH propellants was investigated [461]. The compatibility was evaluated by general corrosion and stress-corrosion tests at temperatures up to 322 K (49°C [120°F]).

The effect of NO concentration levels in N_2O_4 on stress-corrosion cracking of Ti-6Al-4V was investigated repeatedly [462]. Tests were performed on pre-cracked specimens under sustained loading while being exposed to N_2O_4 with various concentrations of NO and at various temperatures for a period of 22–72 h. K_I is the stress field intensity, and K_{ISCC} is the threshold (critical) stress intensity factor. K_{ISCC} corresponds to the beginning of the crack growth before the critical value. When the criterion K_{ISCC} is used, the sensitivity of material to the action of the corrosion medium is characterized by the ratio K_{ISCC}/K_{IC} , where K_{IC} is the stress intensity factor when testing in air. K_{IC} is the plane-strain fracture toughness. Results indicated that at room temperature for a 0.09% NO concentration, the reduction factor K_{ISCC}/K_{IC} was less than 0.53. No additional tests were performed at room temperature. Tests carried out at temperatures up to 338 K (65°C) indicated that K_{ISCC} decreased sharply with NO concentrations less than 0.18%, the lowest measured K_{ISCC}/K_{IC} value being 0.41. The effect of NO concentration levels on stress-corrosion cracking of Ti-6Al-4V welds was not investigated. These test results are in contrast with those reported later, where pre-cracked samples exposed to pure N_2O_4 showed a reduction in K_{ISCC} corresponding only to 20–30%

K_{IC} [463]. It was suspected that the presence of residual fluorocarbons like Freon-PCA that might have been used as degreasing solvents may have aggravated the stress corrosion of titanium alloys in NTO.

A general 220-page survey of stress-corrosion cracking of titanium alloys in any media (not only rocket propellants) gives good background information about this troublesome phenomenon [464].

A test program with full-size tanks verified that this particular tank design fabricated from the Ti-15-3-3-3 alloy was equivalent or superior to the same design fabricated from the Ti-6Al-4V alloy. Solution treatment took place just prior to welding, and final aging was performed after all welding was complete. Twelve-month exposure tests in MON-1, MMH, or hydrazine showed the Ti-15-3-3-3 alloy to be compatible with these propellants [465, 466].

Eventually, very large (1.9 m [75 in] in diameter and 2.7 m [106 in] in length) tanks holding 6800 kg (15000 lb_m) of propellant were made from the Ti-15V-3Al-3Cr-3Sn alloy and qualified for use with NTO in satellites [467, 468]. In this tank the propellants were separated by a common bulkhead.

Because of the Rosetta satellite launch postponement from 2002 to 2004, possible adverse effects of subjecting the titanium propellant tanks to off-loading, decontamination, and subsequent refilling were considered by the European Space Agency [469]. It was unknown whether alterations of chemical composition of residuals in the tanks during this process could cause unacceptable stress-corrosion cracking damage of the tank material. Until then the susceptibility of Ti-6Al-4V alloy to stress-corrosion cracking in the MON-1 environment had been assessed only under nominal conditions of stress and chemical environment that were not sufficiently representative of real cases such as the off-loading, decontamination, and refilling of tanks. A test program was developed that had the objective of assessing the possibility of stress-corrosion cracking in Ti-6Al-4V propellant tanks in the case of tank off-loading, decontamination, and refilling by determination of crack-propagation stress-intensity threshold values of parent plate and weld material exposed to the propellant tank stress and chemical environment expected during off-loading and decontamination.

6.4.4 Compatibility of Other Metals with Dinitrogen Tetroxide

Many metals that are resistant to N_2O_4 by themselves may suffer galvanic corrosion if they are in electrical contact with metals of different electronegativity while immersed in N_2O_4 , in particular if the N_2O_4 is not perfectly dry.

Other metals suitable for handling of N_2O_4 are Inconel and chromium. Chromium is suitable as an electroplating protective coating for other metals, but it has to be free of pinholes.

Copper, bronze, brass, Monel, zinc, cadmium, nickel, and silver are not suitable for use with N_2O_4 .

Interplanetary space probes that are designed to land on planets where we search for life need to be sterilized before launch to make sure that no terrestrial life forms pollute the destination search area. Sterilization by heating imposes severe materials compatibility requirements on all the components [470].

6.4.5 Cleaning and Passivation Methods

6.4.5.1 Cleaning and Passivation Methods for Ferrous Steels

Prior to first usage, tankage and conduits from stainless steel are cleaned with a solution of hydrofluoric acid and nitric acid in water to remove residues of rust and weld spatter. Subsequently, all parts are passivated with 45–55 mass-% nitric acid in water, flushed with water, and thoroughly dried.

Carbon-containing steels can be cleaned and surface-etched with dilute hydrochloric acid, but one must make sure that all traces of chloride are removed before loading with NTO. The recommended passivation method for steel uses an aqueous buffered solution of 0.5% NaOH, 0.5% NaNO₃, 0.25% NaH₂PO₄, and 0.25% Na₂HPO₄.

A seven-step pickling and passivating sequence is supposed to slow down the rate of corrosion if the tank is subsequently filled with NTO or MON [471].

Vandenberg Air Force Base has been the main launch site for DELTA-II, TITAN-3, and TITAN-4, and as such has stored and flown more NTO than any other launch site in the United States. They have developed expertise in cleaning and passivating CRES-304 in ground service equipment and have developed their own cleaning and passivating procedure. Iron leaching from CRES-304 cleaned and passivated by the Vandenberg Air Force Base method has been measured and compared to other stainless steel pretreatment methods [472, 473].

Corrosion rates of CRES-304L coupons in MON-1 have been measured as a function of cleaning procedures, surface layer formation, propellant impurity levels, and exposure duration up to 90 d [474]. Soluble iron leached from the metal was measured as a function of time. Iron contamination in NTO or MON may cause flow decay. Surface treatments tested were combinations of cleaning, pickling, and passivation procedures. Examining and comparing the surfaces of untreated and passivated coupons by XPS-ESCA has revealed significant differences in the surface species present. The results indicated the need for a spacecraft-grade MON with lower water and chloride content than that allowed by military specifications.

The flow-decay problem associated with NTO has been an important factor in the design of small bipropellant propulsion systems. The objective of a program established at the JPL has been to alleviate this problem by **(1)** developing a process to purify NTO to a level of contamination that will minimize the precipitation of iron-contaminated species, and **(2)** establishing component cleaning and passivation procedures that will prevent recontamination of the propellant [398]. Although a number of potential methods for purification of NTO exist, the method employing molecular-sieve column treatment appears to offer the advantages of simplicity of implementation,

relatively low cost, and proven capability to operate in the field as well as in the laboratory. In general, the molecular-sieve adsorption column treatment of mixed oxides of nitrogen (e.g., MON-1 and MON-3) results in little change in nitric oxide (NO) concentration (well within specifications), efficient removal of contaminant iron and other metals, efficient removal of water (i.e., HNO_3 and H_2O) when the column is activated, apparent removal of chloride impurity, and no introduction of deleterious material from leaching of the zeolites employed.

One common multi-step sequence of CRES or Ti alloy tank cleaning and passivation methods used a solution of an industrial cleaner such as Turco 4181 with ultrasonic agitation for degreasing; deionized water rinsing; nitrogen blow drying; pickling with a solution of 20–25 vol-% HNO_3 , 2–5 vol-% HF, and the rest deionized water at 293–318 K (20–45 °C) for 10–25 min; deionized water rinsing; nitrogen purge; passivation with 20–45 vol-% HNO_3 at 303–313 K (30–40 °C) for 15–20 min; isopropanol rinsing; and nitrogen purge drying [399].

The JPL, in support of the Galileo interplanetary probe propellant loading and unloading effort, has evaluated several cleaning and passivation methods for CRES-304L by measuring the amount of iron leached in either military-specification MON or “dry” MON during 14 or 90-d immersion at 316 K (110 °F). Four different ten-step cleaning/passivating methods were compared, which differed in the type of acid used for step 6, using either citric acid, 10% HNO_3 , or 30% HNO_3 or no acid at all. The rates differed widely for military-specification MON but were very similar for dry MON-1. The passivating oxide layers produced by the various methods were analyzed by XPS, in particular for the Fe/Cr ratio. The rate of iron leaching was very high during the first 20 d and then leveled off during the remainder of the 90-d tests.

6.4.5.2 Cleaning and Passivation Methods for Aluminum Alloys

Anodized aluminum is not any more resistant toward N_2O_4 than non-anodized aluminum. Up to this time, no coatings have been found that would make aluminum more resistant to N_2O_4 , in particular none that would make it more resistant toward moist N_2O_4 .

One of the attempted surface-preparation methods recommends etching the surface with chromic acid solution in water until the surface is evenly clean, and then rinsing and passivating with 45% HNO_3 .

Reactivity of NTO with Cleaning Agents

The reactivities of several selected halogenated precision-cleaning solvents with MON-3 have been determined by analysis of the rates of formation of halide ion decomposition products [475]. The solvents tested were Asahiklin AK 225, Asahiklin AK 225 AES, HFE 7100, HFE 7100 DE, Vertrel XF, Vertrel MCA, Vertrel MCA Plus, 1,1,2-trichloro-1,2,2-trifluoroethane (CFC-113), and trans-1,2-dichloroethylene (DCE). HFE 7100 DE, Vertrel MCA, and Vertrel MCA Plus showed significant reactivity with MON-3 oxidizer.

6.4.6 Hypervelocity Impact Reactions with Dinitrogen Tetroxide

Any oxidizer contained in a metal vessel is liable to react with the metal when the tank is hit by a hypervelocity projectile, such as a meteorite or orbital debris. The main concern has been with tanks that are filled with liquid oxygen or dinitrogen tetroxide.

The impact sensitivity of commercially pure titanium, Ti-6Al-4V, and precipitation-hardened 15-7 Mo stainless steel was measured under a range of stimuli, including shearing, scraping, galling, and impact by massive strikers and high-velocity bullets [433, 438]. Titanium ignition was rarely evidenced by sparks or noises and usually resulted in small fused areas on the impacted metal surface. The reaction did not propagate, although there was sufficient NTO present to allow complete consumption of the metal. The nitrogen formed by the reaction may impede access of fresh oxidizer to the burning metal surface. Precipitation-hardened stainless steel PH-15-7Mo was not impact sensitive in liquid NTO. The falling-hammer impact apparatus used hammers weighing 4.5, 9.7, and 11.6 kg and were dropped from a height of 3 m (10 ft). The ignition frequency of titanium A55 as a function of impact energy in NTO was about the same order of magnitude as observed for fluorine or oxygen. With titanium, the impact threshold energy required for ignition decreased with time spent in the loaded state: About three times more energy was required for freshly covered samples compared to others stored for 24 h in the wetted state. Additional storage for up to 3 months did not change the sensitivity any further. Most of the tests were conducted with specimens cooled to near 273 K, except the bullet-impact tests, which were conducted at ambient temperatures between 288 and 300 K. For the bullet-impact tests, containers were made from 7.5-cm sections of 19-mm grade A titanium tubing and were filled to three-fourths of their capacity. The major concern about freshly sheared metal surfaces igniting in NTO is with the design and operation of pyro valves.

6.5 Non-metallic Materials of Construction for Dinitrogen Tetroxide

There are several literature summaries on the compatibility of polymers with NTO and similar corrosive oxidizers [476–478].

6.5.1 Elastomeric Materials for Gaskets and Seals

During the development of the Titan-II system, a large number of the failures were blamed on lack of resistance of non-metallic materials (gaskets, O-rings, bushings) once they were exposed to N_2O_4 [345]. There are numerous literature summaries on elastomeric material compatibility with NTO and other propellants [479]. These are needed for gaskets, O-rings, expulsion bladders, and personal protection equipment.

Valve seats and pistons may suffer worse degradation while exposed to N_2O_4 (NO_2) vapors than when in the liquid phase. Kel-F may suffer degradation of surfaces that are in frictional contact with each other. Teflon, which is otherwise a very resistant

polymer, caused problems because NO_2 vapors may diffuse and permeate through this polymer

Teflon may also swell once it is immersed in N_2O_4 . This can lead to blocked valves or frozen pump impellers.

Teflon may cold-flow when under compression. The cold flow can be reduced by filling the polymer with inert powders and fibers. Glass powder-filled Teflon (brand name Fluorogreen) can be used for valve seats. Teflon-impregnated asbestos has been recommended for gaskets and washers (brand names Armstrong AT-810 and AT-812).

The following reports give more information on non-metallic materials for use with N_2O_4 , such as polyvinylidene fluoride (Kynar) [480, 481]. The development of a nitroso terpolymer containing pendent carboxy groups resulted in a nitroso polymer with greater crosslinking versatility. This polymer could be cured with metal salts of organic and fluorocarbon acids, epoxy compounds, and epoxy/metal oxide mixtures. These carboxy nitroso rubber vulcanizates were resistant to N_2O_4 , showing no change in mechanical properties after 90 d of total immersion at 347 K (165 °F). See also [482].

A set of elastomer seals previously considered unsuitable for exposure to N_2O_4 has been re-examined and found to be qualified for long-term use with N_2O_4 [483, 484].

Different fluoropolymers were evaluated as bladder materials for NTO or hydrazine [485], in particular for an advanced liquid propulsion system under development at the JPL [486]. Fluoroelastomers were expected to be resistant to hydrazine as well as to dinitrogen tetroxide, but permeability problems persisted.

Alternate repair methods have been considered for situations in which a threaded connection starts leaking small amounts of NTO, MON, or MMH and cannot be stopped from leaking by tightening of the cap or B-nut with a wrench. A clamshell repair kit that wraps and clamps around the leaking fitting has been developed for last-minute repairs of small leaks that otherwise would require a launch postponement and expensive off-site repair [487].

Additional work on long-term exposure of Kalrez to NTO was conducted at Aerospace Corporation [488, 489].

The weight and Shore A hardness of Kalrez 1045, a perfluorinated copolymer, were determined from samples from two different lots after exposure to dinitrogen tetroxide at two different pressures, 7320 kPa (72.5 atm) and 101 kPa (1 atm), for times ranging between 1 and 80 d and for observation periods up to 21 days following their exposure [490]. The largest changes occurred in the first 8–10 d of exposure. The weight increased between 15 and 30%, and the Shore A hardness declined from 83 to 60. Both weight and hardness partially recovered to their original values after removal from liquid N_2O_4 and drying in air. However, samples exposed for more than 1 d never fully recovered. The chemical stability of the Kalrez as a function of time exposed to N_2O_4 was monitored with solid probe-mass spectrometry. The results indicated that there was no main chain scission for the first 30 d of exposure. Loss of the pendant groups from the main chain was observed within 16 h. Loss of the pendant group from the crosslink site monomer and loss of the crosslink itself occurred after 150 h of exposure

to N_2O_4 . The overall results indicated that Kalrez 1045 exhibited exceptional stability to N_2O_4 , and seals manufactured from this material should be superior to the butyl rubber that had been employed in the oxidizer circuits of some launch systems.

O-ring seals of selected elastomeric and compliant materials were evaluated for resistance to liquid rocket fuels in a simulated end-use test [491, 492]. The candidate elastomers were placed under compression in closed cells and exposed to the liquid and vapor of NTO in direct contact with the O-ring seals at 296 K (73 °F) for extended periods of time. Rate of fuel loss through the seal and the change in physical properties of the seal materials were determined. Metal-clad and polyethylene-encapsulated elastomeric O-rings were also tested for resistance to NTO at 296 K (73 °F). The effect of temperature on elastomer endurance was determined by exposing the O-rings to NTO at 344 K (160 °F). The effect of direct immersion in liquid rocket fuel on the physical properties of the seal materials was investigated by immersing promising O-ring candidates in NTO.

A continuously recording permeation measurement apparatus was designed and used to characterize the permeation of NO_2 through Teflon [493]. In view of all the known data about NO_2 permeation through Teflon, one wonders why Mars Observer was flown with only two Teflon check valve seats separating the NTO from the pressurant gas space and MMH feed lines during the 11-month cruise phase from Earth to Mars, resulting in the loss of the spacecraft when the system was activated prior to Mars orbit insertion on 21 August 1993. Mars Observer was scheduled to perform an orbital insertion maneuver on 24 August 1993. However, contact with the spacecraft was lost on 21 August 1993. A likely reason for spacecraft failure was the leakage of fuel and oxidizer vapors through the improperly designed polytetrafluoroethylene (PTFE) check valve to the common pressurization system. During interplanetary cruise, the vapor mix had accumulated in pressurant lines, resulting in explosion and their rupture after the system was activated for course correction [494–496]. A similar problem would later cripple the Japanese Akatsuki Venus Climate Orbiter space probe in 2010.

An O-ring material used in storable propellant components on many NASA spacecraft designs was discontinued by the manufacturer, and NASA's stockpiles were expected to be depleted soon thereafter. The NASA Engineering and Safety Center (NESC) initiated a materials compatibility characterization effort to evaluate multiple replacement material options. Material properties of multiple replacement candidates were tested, looking at weight change, swelling, hardness, compression set, and tensile strength in representative environments to help identify suitable replacements [497].

6.5.2 Elastomeric Materials for Positive Expulsion Diaphragms and Bladders

Teflon is compatible with N_2O_4 , but NO_2 vapors permeate Teflon quite quickly. It was attempted to reduce the permeability by coating the Teflon with vapor-deposited aluminum films [498]. It was difficult to achieve the strength and ductility required for a liquid propellant expulsion bladder. Teflon-aluminum laminates were produced

that had no permeability to N_2O_4 or NO_2 , with modulus below 125ksi and tensile strengths in excess of 4 ksi.

Various elastomers were evaluated at the JPL for large hemispherical expulsion bladders for dinitrogen tetroxide and hydrazine in an advanced liquid propulsion system (ALPS) where propellants were to be stored for 1 year at 293–323 K without degradation of either the expulsion bladders or the propellants [499]. The original design of the ALPS envisioned a pair of collapsible bags containing hypergolic propellants ($\text{NTO}/\text{N}_2\text{H}_4$) within a common pressure vessel. In retrospect, this was a two-component bomb waiting to explode. Permeation of both NTO and N_2H_4 into the pressurant gas space might have caused ignition or deposition of corrosive reaction products. It was then realized that polymeric membranes alone are not suitable for such a design. Adding an “ NTO getter” that would continuously remove the permeated NO_2 from the gas side of the bladder would overly complicate the system. Most “compatible” polymers such as polyfluorocarbons are swelled and softened by contact with NTO . Silastic LS-53, for instance, swells to 300% of its original volume in NTO . Metallic platings on Teflon intended to act as a permeation barrier have failed because of swelling of the elastomer when the Teflon side was exposed to NTO . The swelling problem may be aggravated by the markedly anomalous coefficient of thermal expansion behavior of Teflon, which undergoes a five-fold increase between 379 and 433 K and then returns to its former value at the 444-K mark. A number of fluoropolymers were evaluated for the bladder application, but none was found to meet the strength, compatibility, and permeability criteria.

Silastic, Fluorel, Viton A, Viton B, and cured polyethylene were tested by immersion in NTO for 1 and 7 d at room temperature. All elastomers showed substantial swelling. Hydrocarbon polymers swelled less than fluorinated polymers did. Viton B showed the best resistance to NTO [500–502]. Carboxy nitroso rubber was recommended for long-term exposure to NTO at 347 K (165 °F), while resin-cured butyl rubber was satisfactory only for limited application [503].

Fluorocarbon bladder films must be flexible and have low permeability for NO_2 . One criterion requires a low-molecular-mass polymer, and the other requires a high-molecular-mass polymer. One must optimize the merits of high-molecular-mass, high-melting, rigid Teflon TFE and its lower-molecular-mass, lower-melting, and more flexible copolymer, Teflon TFE fluorocarbon resin. The high/low molecular-mass polymer proportions can be pre-assessed by stress-strain analysis of the tensile curve [504].

When the permeation of NO_2 through PTFE membranes between 0.04 and 0.14 mm thick (0.0015 and 0.0057 in) was tested in the temperature range of 202–389 K (30–116 °C), the diffusion and permeation coefficients were found to be independent of membrane thickness [505]. For NO_2 – N_2O_4 , the temperature dependence of the permeation rate was complex, partially because it was dependent on the $\text{N}_2\text{O}_4 \rightleftharpoons 2\text{NO}_2$ dissociation equilibrium. Unlike permanent gases tests in the same series of experiments, NO_2 interacts strongly and reversibly with the polymer.

Standard Teflon/aluminum laminate bladders employed as NTO and MMH zero-gravity propellant management devices on the Mariner Mars 71 space probe failed because of cracks and tears near an aluminum seal ring that formed the mouth of the bladder [506]. These failures occurred during flight-acceptance tests with inert solvents (Freon TF and isopropanol) used as simulant fluids. It was found that one of the laminate polymers, FEP 120, was particularly solvent sensitive, and it was then eliminated from future laminates for expulsion bladders.

When selecting materials for expulsion bladders, there is a dual concern: permeability of the polymer material for the propellant in one direction and permeability of the material for pressurant gas in the other direction. These concerns were adequately addressed in the construction of the propellant tanks for the five Lunar Orbiter missions that were launched between August 1966 and August 1967 and operated for up to 339 d in space, mapping the moon in preparation for manned lunar landings. During a simulated mission ground test, a comparison was made of the nitrogen permeation through a Teflon bladder and a laminated Teflon-aluminum bladder. With plain Teflon, pressure had equilibrated on both sides of the bladder within 100 h, whereas no detectable nitrogen permeation took place with the laminated Teflon-aluminum bladder [507].

Viton-B, Kel-F, and modified poly(cyclized 1,2-polybutadiene) tolyl urethane (CPBU) elastomers were tested for use in NTO expulsion bladders [508, 509]. In parallel, valve seat and gasket materials were developed for use in dinitrogen tetroxide and Aerozine-50. One of the materials developed for this oxidizer application was AF-E-124D [510]. AF-E-124D is a terpolymer of tetrafluoroethylene, perfluoromethyl vinyl ether, and perfluorophenyl vinyl ether. See also [511].

Seamless Teflon positive expulsion bladders were used for NTO, MMH, and Aerozine-50 propellants on the Apollo command module, service module, lunar descent module, and even on the S-IVB upper-stage RCS [512]. A similar bladder was used for MMH on the unmanned Lunar Orbiter velocity control system.

Composite Teflon-aluminum foil bladders were evaluated for the Surveyor lunar lander vernier propulsion system in an effort to reduce helium permeation and propellant (MON-10 or MMH/H₂O) saturation with pressurant gas [513, 514]. If the propellants were partially or fully saturated with helium, the large quantities of gas coming out of solution and the resulting two-phase flow decreased the dynamic response of the vernier engines. Propellant permeation into the ullage space was only a minor problem.

Bladders tested were initially made of multiple sprayed layers of tetrafluoroethylene (TFE) and fluoroethylene propylene (FEP). Others used a “bag-in-a-bag” design. TFE was manufactured similarly to a sintered-powder metallurgical part by compressing the powder. FEP was similar in character to a true thermoplastic material. The major problem was bladder tearing during three-axis vibration, in particular at the lower temperature range [515, 516].

Elastomers developed for service with dinitrogen tetroxide included AF-E-124D (perfluorinated polymer) and carboxynitroso rubber/HYSTL composites. Polymerizations were conducted to prepare a perfluorinated elastomer cured by a (perfluoro) covalent mechanism. Diaphragms molded from AF-E-124R, intended for NTO, had problems with sticking to the mold and poor compaction in the seal bead.

6.5.2.1 Elastomeric Materials Degradation Mechanisms

The mechanism and cause of N_2O_4 attack on polymeric elastomers was studied by measuring the effects of interaction, crosslinking, and structural variations in polymers [517, 518]. Polyethylenes with varying molecular weight, degree of branching, and unsaturation were studied by IR spectroscopy to identify the weak links in the molecule where N_2O_4 attack weakens the structure. Mechanical changes in polymer strength were determined by linear creep measurements, permeability to N_2O_4 , and chemical changes under N_2O_4 exposure. Polymers that suffered chain scission exhibited much larger irreversible elongation than before exposure. Results indicated that the best mechanical performance with respect to resistance of polyethylene to N_2O_4 was offered by polymers of intermediate molecular weight and containing little vinyl side group unsaturation. Fluorinated ethylene propylene polymer showed little degradation after 7 d of exposure to liquid N_2O_4 .

6.5.2.2 Insulating, Coating, and Encapsulating Materials for N_2O_4 Service

Neopren, Mylar, Hypalon, Micarta thermosetting plastic, latex rubber, and natural rubber are not suitable for service with N_2O_4 . In particular, these materials should not be used as insulation in electrical installations where they may be exposed to N_2O_4 or NO_2 . Electrical cables in Titan-II underground installations were all insulated with butyl rubber.

Thermal conditioning jackets are often insulated with foamed-in-place polyurethane foam. This material may auto-ignite if it comes in contact with N_2O_4 .

A liquid level indicator that had been encapsulated in Teflon failed because sufficient NO_2 vapors had diffused through the plastic sheath such that the electrical sensors were destroyed. An epoxy-coated CRES-304L sample suffered microscopic cracking and blistering of the coating and surface pitting beneath the coating [408].

6.5.3 Lubricants for N_2O_4 Service

Common lubricants are not allowed for use with N_2O_4 . One has to be extra careful that all components are carefully degreased before allowing them to come into contact with N_2O_4 . Not even lubricants that are considered acceptable for use with liquid oxygen can be safely used with N_2O_4 because they often react with N_2O_4 . The following lubricants have been recommended: Dow Corning DC-II, Silicone Lubricant, and Drilube Type 822-MMSN 3068; Nordcoseal-147 or DO-234-S as well as NA2-205-

2-Alochlor-1254-Monsanto; and Molycote-Z and Fluorolube (may be useable). Reddy Lube-100 is not suitable because it will harden after a short time.

Lubricants considered acceptable for NTO service are Castrol Braycote 601, DuPont Krytox 204AC, and Solvay Plastics Fomblin Y25. Fomblin PFPE fluorinated lubricants are resistant to aggressive chemical environments, high temperatures, and wide working-temperature ranges.

Perfluorinated greases are typically used as a thread lubricant in the assembly of non-welded NTO oxidizer systems. These greases, typically a perfluoroalkylether with suspended PTFE micro-powder, have attractive lubricating properties toward threaded components and are relatively chemically inert toward NTO oxidizers. A major drawback, however, is that perfluoroalkylether greases are soluble or dispersible in NTO and can contaminate the propellant and deposit in other parts of the system (valves, filters, injectors). This problem is exacerbated when propellant is circulated or transferred between storage units and test stands, resulting in widespread contamination. Contaminated NTO fails the non-volatile residue (NVR) specification analyses and may have negative effects on test hardware performance and lifetime. Consequently, removal of the grease contaminants from NTO may be highly desirable. Methods for the removal of perfluorinated grease components from NTO oxidizers, including distillation, adsorption, filtration, and adjustment of temperature, were investigated [519]. Krytox 240 AC is a mixture of a perfluoroalkylether (73–82% Krytox 143 AC oil) and PTFE (18–27%). Solubility or dispersibility data for the perfluoroalkylether oil (Krytox 143 AC) component of Krytox 240 AC and for Krytox 240 AC itself in NTO were determined. The NVRs of Krytox 240 AC-spiked NTO (25 g in 360 mL NTO, agitated after filtration through a 0.2- μm PTFE filter) taken at two different times after spiking were $29 \pm 1 \text{ mg/L}$ after 3 h of contact time and $200 \pm 20 \text{ mg/L}$ after 4 d of contact time. The NVRs of Krytox 143 AC-spiked NTO that were equilibrated 5 d and then filtered through a 0.2- μm PTFE filter and determined sequentially were three to four times as high. Purification of the contaminated NTO was attempted by passing it through adsorption columns filled with high-surface-area aluminum oxide, diatomaceous earth, or porous PTFE beads. Column adsorption with aluminum oxide removed approximately 30% of the spiked Krytox 143 AC NVR.

Graphite bearings in pumps and graphite gaskets in the packing of valve stems may swell during exposure to NTO or MON. A soak test of four kinds of graphite sealing material was performed in N_2O_4 to verify the compatibility of graphite material and N_2O_4 [520]. Variables that influenced the sealing performance of graphite material were graphite porosity, impregnating resin, graphite substrate material, graphite element, and microstructure. Analysis results indicated that the graphite impurities and microstructure had an important influence on resistance graphite material to N_2O_4 . See also [521, 522].

6.5.4 Sealants for N_2O_4 Service

If one wants to make a preliminary seal of a connection that does not need to be opened, one can seal it with a mixture of sodium silicate (“water glass”) and graphite powder.

6.6 Plume Contamination by Dinitrogen Tetroxide

It is common practice to vent unused dinitrogen tetroxide after geostationary satellites have arrived at their intended orbit, having used their bipropellant LEO-GEO transfer and apogee insertion thrusters. Venting unused propellants prevents them from sloshing around and causing center-of-gravity shifts. However, the slowly diffusing cloud of corrosive dinitrogen tetroxide may adversely affect other components of the satellite, such as magnesium fluoride anti-reflection coatings on solar panels and lenses [523].

7 Components for Dinitrogen Tetroxide Service

7.1 Flight Tanks for Dinitrogen Tetroxide Service

Reading through the rocket propellant literature, it becomes apparent that the two most difficult propellants to design long-term storage, lightweight, flight-qualified propellant tanks for are dinitrogen tetroxide and anhydrous hydrazine. Some of the literature on NTO propellant tanks is summarized in Table 45. Many of the reports listed in this table may not be specific for NTO but concerned more than one propellant. Commonalty of tanks is desired for designing a satellite. It appears that once a tank design is able to handle the more corrosive oxidizer, a similar tank can be safely used for the less corrosive fuels. Although the same tanks or very similar tanks can also be used for IRFNA or hydrazine-type fuels, the list of propellant tanks will not be repeated in the IRFNA or fuels section.

Table 45: Summary of literature on dinitrogen tetroxide propellant tanks.

Topic	Author	Year	References
Construction materials for NTO containers	Evans	1960	[401]
High-strength materials for liquid propellant tankage	Ng and Walsh	1969	[524]
Liquid rocket metal tanks	Wagner and Keller	1974	[525]

In early 1966, two Apollo main propulsion system titanium alloy tanks successfully completed 30-d exposures to N_2O_4 under maximum operating stress (approximately 100ksi wall stress) [449, 526]. These tanks were about 1.29 m (51 in) in diameter and about 4.25 m (14 ft) in length, with wall thickness of approximately 1.4 mm (0.055 in). In January 1965, a smaller RCS titanium alloy tank failed a similar 30-d test at approximately the same stress level. Failure analysis by Bell Aerosystems and North American Aviation concluded that the failure mode was stress corrosion, and the probable cause was contamination by chlorides prior to heat treatment. Six cracks were observed in three discrete areas of the tank wall. This tank had a Teflon bladder that, theoretically, isolated the titanium from the N_2O_4 . To be safe, however, ten additional tanks (without bladders) were put into testing at Bell to represent a sample of production runs to ensure that the contamination problem was an isolated one or that it was associated with a particular production period. Thirty-four hours after the tanks had reached test temperature 314 K (105 °F) and pressure, the first tank failure occurred. Three other tanks burst within the next 9 h of the test. When the failed tanks were examined metallurgically, thousands of stress-corrosion cracks per tank were found. These cracks varied from very shallow (0.07 mm [0.003 in]) to cracks extending through the 0.43-mm-thick (0.017 in) wall. NASA and the Apollo contractors were faced with a serious materials compatibility problem.

7.1.1 Propellant Expulsion Bladders for Dinitrogen Tetroxide Service

The majority of NTO propellant tanks nowadays are surface tension tanks; however, smaller tanks may still use bellows, pistons, reversible diaphragms or collapsible bladders. There have been extended efforts to develop NTO-compatible elastomers for bladders and diaphragms, but in the end the permeation rates were too high with all the materials tested. It was attempted to reduce the permeation rates by metallizing the bladders or diaphragms. Other reversible diaphragms were made from soft aluminum [527] or stainless steel instead of elastomers. The problem with reversible metal diaphragms is that they can be reversed only once, and pre-flight tests for expulsion efficiency will consume a good tank.

The propellants for the Surveyor lunar lander vernier thrusters were kept in tanks with Teflon positive expulsion bladders, but that was only a very short mission in transit to the moon [514, 528]. The Apollo service module RCS needed to operate under a wide variety of acceleration and zero-gravity loads, so the propellant needed to be contained in a bladder [512, 529].

It was attempted to form a flexible rollonet rolling-diaphragm propellant expulsion device inside a tank by chemical vapor deposition of aluminum from an atmosphere of decomposing alkyl aluminum [530]. Such a tank could be used for NTO and other propellants.

7.1.2 Propellant Expulsion Pistons for Dinitrogen Tetroxide Service

Atlantic Research developed a tank with a traveling piston ring that also held a reversible diaphragm to more closely adapt to the hemispherical concave dome at either end of the domed cylindrical tank [531]. The elastomer seals on the piston ring were separated from the corrosive propellant by a metal shear strip that would rip when the tank was activated. By the time the piston ring had traveled the full length of the cylindrical section, the diaphragm in it would have reversed and now contoured the dome at the other end of the tank, thus improving expulsion efficiency.

7.1.3 Surface Tension Tanks for Dinitrogen Tetroxide Service

Surface tension and contact angles of liquid propellants must be known in order to design surface-tension tanks for use in a zero-gravity environment in space. Surface-tension tanks have fine-mesh screens in the forms of chimneys, vanes, and galleries to collect and hold propellants in position near the tank outlets, even in a zero-gravity environment [532–534]. Pressurant gas entrainment is a major operational problem with surface-tension tanks. The tanks have bubble traps to retain gas bubbles and prevent them from flowing out with the propellant. Pressurant gas entrainment is inevitable toward the end of the useful life of a satellite after the propellant supply is exhausted.

Because the wire mesh exposes a large surface area to the propellant, wire mesh material compatibility is an important design criterion. Traditionally, most surface-tension PMDs have been made from stainless steel wire, but the tank shell would be a titanium alloy. That sets up the potential for galvanic corrosion of dissimilar metals. It would be better if both the PMD and the shell were made from the same material, but it has been difficult to extrude titanium into thin wires and to weave titanium mesh.

The Space Shuttle RCS and OMS tanks used surface-tension PMDs to collect propellant under zero-gravity conditions [535]. The surface-tension screen was a 325×2300 twilled double-Dutch weave (TDDW) pattern from CRES-304L. The surface area was approximately 8 cm^2 per cm^2 of screen. Such a large surface area had the potential of leaching a large amount of iron and causing flow decay after the iron nitrate saturation of the NTO was exceeded. In a test program at NASA WSTF, the iron leaching from the surface-tension screen was tested by exposing screen samples to 50 mL of MON-3 at 300 K (80 °F) for 1–90 d [11, 536]. The samples were cleaned using the same procedure as that used by the tank manufacturer for flight hardware, but that procedure did not include a nitric acid pickling/passivation step. The off-loaded propellant was analyzed for soluble and particulate iron by passing it through a $5\text{-}\mu\text{m}$ membrane filter. The iron production rate decreased steadily during the 90-d period from $2 \times 10^{-6} \text{ g d}^{-1} \text{ in}^{-2}$ to $0.08 \times 10^{-6} \text{ g d}^{-1} \text{ in}^{-2}$. The iron was mostly in the soluble form, and only a little particulate was retained on the screen.

Instead of wire-mesh assemblies, stacks of etched discs can also be used as surface-tension PMDs [537, 538], and instead of etched discs, double-perforated plates can also serve as capillary barriers in surface-tension PMDs [539]. The gap between the plates fills with liquid. The advantage of either system is that there is a wider choice of metals to make the discs or plates from.

In order to investigate the corrosion behavior of CRES-304 stainless steel propellant retention screens in surface-tension propellant tanks, flight-standard devices were stored for 35 months in MON-1 at 323 K (50 °C) [540]. There was no degradation of the screen's bubble point, indicating that chemical reaction of the materials, if any, was rather small and did not impact the performance of the screen. The corrosion rate was in the order of 2×10^{-6} mm/year. Using this corrosion, the worst-case iron content in the oxidizer of a satellite was calculated.

The NEAR Shoemaker space probe was the first space probe to enter into an orbit around the asteroid Eros and eventually hard-land on it. In order to meet a tight development schedule, the oxidizer tank, with a diameter of 19 in, was a space-qualified diaphragm Ti-6Al-4V shell tank originally developed for the EXOSAT mission [541]. It was modified by

- elimination of the elastomeric diaphragm
- removal of the diaphragm support ring
- addition of an outlet tube near the tank equator
- modification of the pressurant and propellant tubes and tube supports
- addition of a vortex suppressor

A surface-tension PMD oxidizer tank for the Orbital Sciences Star-2 platform, which has flown on more than two dozen commercial geostationary communication satellites, was subjected to simulated launch conditions on the vibration table, and its slosh dynamics were modeled by a detailed three-dimensional computer program [542]. The vane-sponge-type PMD was custom-designed for the Star-2 spacecraft mission. To minimize cost, an existing tank shell was selected as the baseline design and was slightly modified for the mission. No modification was done to the tank membrane to maintain qualification by similarity. The propellant tank shell was constructed of solution-treated and aged (STA) Ti-6Al-4V. This material provided excellent strength-to-weight characteristics. The PMD was made of annealed Ti-6Al-4V and commercially pure titanium material. The MEOP was 2.068 MPa at 323 K (300 psia at 122 °F), the proof pressure was 2.585 MPa (375 psia), and the burst pressure was 3.10 MPa (450 psia). The inlet/outlet ports were made of Ti-3Al-2.5V. The expulsion efficiency was 99.79% minimum for depletion during liquid apogee engine firing, and the nominal NTO oxidizer load was 223.2 kg (492 lb). The propellant in the tank would remain near the outlet in the worst-case accidental flat spin at 5 rpm, and the perforated sheet could keep the gas from penetrating into the pick-up assembly.

7.1.4 Long-Term Tank Storage Tests

An effort to establish the operational limit of allowable iron in NTO for system worst-case conditions (2ppm Fe) and to verify that this operational limit would not be exceeded after missile long-term (10-year) storage in the field was based on a combination of existing flow-decay data from the literature and experimental testing of a representative PEACEKEEPER missile fourth-stage oxidizer tank. At Rocketdyne, a flight-worthy PEACEKEEPER propellant storage assembly consisting of a Ti-6Al-4V shell and nitric acid-passivated CRES-304L TDDW screens was filled with MON-1 and kept in storage for 8 months at ambient temperature; oxidizer samples were drawn periodically and analyzed [543]. The initial iron content prior to loading the oxidizer had been reduced to 0.23ppm. A rapid rise of iron content to 0.5ppm Fe was observed during the first months, and after that the rate of iron leaching dropped to zero. The sludge formed during the initial propellant pickling settled, and a protective film formed on the steel. The results were more encouraging than similar tests conducted earlier at Bell Aerospace.

At the date of the first report, a significant number of liquid propellant tanks, fabricated by typical production methods of forming and welding and subjected to the same degree of inspection and quality-control documentation as production tankage, had been evaluated in storage testing for nearly 2 years. A number of leaks were encountered in all three types of tankage metals, aluminum, steel, and titanium. In general, the failures were attributed more to quality discrepancies during fabrication and welding than to a lack of compatibility of the metals themselves [431]. It was observed that if the relative humidity was of the order of 30% or lower, the nitrogen dioxide vapor dissipated into the atmosphere and did nothing to aggravate the leakage. If the relative humidity was of the order of 40% or greater, however, it did not dissipate, but rather hydrolyzed, forming dilute nitric acid on the exterior surface in the immediate vicinity of the leak. The action of the nitric acid was to enlarge the original leakage path, working inward toward the source of the leak.

Tank storage tests under extreme conditions of relative humidity and temperature (constant 303 K [85 °F] and 85% relative humidity for oxidizer systems and cycling between 294 and 339 K [70 and 150 °F] for fuel systems) in progress for 3–4 years indicated that leakage of propellant can occur as a result of improper weld joint design, inadequate quality control in fabrication, and insufficient acceptance-leakage testing. During this period a total of 12 tanks were analyzed for cause of failure [544]. Later reports contained additional metallurgical examinations of failed tanks and connecting tubing [545–547]. Stress-corrosion cracking susceptibility of the tank material in combination with the propellant and trace quantities of foreign compounds/elements in the propellant can aggravate the situation.

Tanks that had held NTO and were stored in a storage environment at 303 K (85 °F) and 85% relative humidity for several months were emptied, cleaned, and dissected for metallurgical analysis [548]. The corrosion effects of the stored propellants on the internal metal surfaces were negligible, with no serious degradation of strength or

structural integrity occurring. Corrosion occurred primarily due to pitting, gas and liquid phase interactions occurring during storage, manufacturing defects, and corrosion occurred at the manifold tubing welds.

7.2 Valves for Dinitrogen Tetroxide Service

It would be tempting to make valve bodies from titanium alloys instead of stainless steel because titanium alloys are lighter weight and have better resistance to corrosion. This applies to solenoid valves and pyro valves. The selection of titanium alloy for a latch valve resulted in a low-weight (308 g [0.68 lb]) valve configuration and avoided the potential of ferric nitrate formation and flow decay in the oxidizer [549]. However, freshly sheared metal surfaces in pyro valves, in particular titanium alloy surfaces, may ignite in NTO [550].

7.3 Pressure Regulators for Dinitrogen Tetroxide Service

Dinitrogen tetroxide vapor-phase corrosion was suspected of having caused the failure of a ground-test helium pressurizing gas-pressure regulator at NASA WSTF [551]. In a subsequent failure investigation, coupons of CRES-304L and 15-5PH with several different surface finishes were exposed to MON-3 vapor for 14, 27, and 100 d. Post-exposure visual examination did not show any significant corrosion. Based on water-soluble iron ion analysis in the water rinse of the coupons, the corrosion rates in the vapor phase were similar to and not worse than those in the liquid phase in MON-3.

The INTELSAT 603 satellite was stranded in a low-earth orbit for 797 d after the separation of the TITAN-III upper (second) stage from the satellite failed, awaiting Space Shuttle rescue. In the storage orbit, helium leakage was observed through the primary pressure regulator and then through the redundant helium regulator. During this time, the pressure-regulation panel of the bipropellant propulsion subsystem was engaged. Flight-pressure telemetry indicated primary regulator leakage, eventually followed by leakage through the backup regulator [552]. The malfunction of the oxidizer and fuel-side pneumatic check valves followed Space Shuttle deployment, evidenced by failure of the propellant tanks to maintain regulated pressure during liquid apogee thruster firing.

A pressure-transducer diaphragm failed, causing N_2O_4 to leak into a volume filled with silicon oil and leading to an explosion and the release of approximately 2.8 L (3 quarts) of liquid NTO [553] Page 63–65; [554]. In March 2003, the NASA WSTF was performing a life-cycle test of a fast-acting valve, using NTO as the test fluid [555]. The test system was designed to circulate NTO from one 55-gallon cylinder through the test article to an identical receiving cylinder and back again. The test system was constructed of ~50 ft of $\frac{3}{4}$ -in and $\frac{1}{4}$ -in stainless steel tubing. All wetted components in the

test system were compatible with NTO. The supply of NTO was pressurized to 2.07 MPa gauge (~300 psig). The test article was opened for 80 ms each cycle and had a flow rate of 0.86 kg/s (1.91 lb/s). After ~36000 cycles had been performed, an explosion was heard from the test cell. The video camera in the test cell was quickly obscured by a cloud of NTO, preventing the test team from being able to immediately determine the cause or location of the leak. The test system was quickly powered down, and all valves were closed to minimize the spill. Test personnel were then sent into the test cell with totally encapsulating suits to survey the damage and begin the recovery efforts. During the inspection, it was immediately obvious that a pressure transducer on the test article inlet line had failed catastrophically, releasing liquid NTO into the test cell. The test team recovered the inlet port and body of the pressure transducer and approximately three-quarters of the failed diaphragm. The manufacturer of the pressure transducer had not made the users aware that the transducer contained silicone oil.

7.4 Filters for Dinitrogen Tetroxide Service

With flow decay observed on many spacecraft in orbit and during ground testing, the sizing of filters becomes a critical spacecraft design issue to prevent clogging of vital flow passages. If the filter-screen openings are too small, the pressure drop may become prohibitive. If the particle-retention capacity of the filter chosen is too large, one pays a weight and space penalty.

The GALILEO Jupiter space probe was the first bipropellant propulsion system to go on an extended interplanetary mission. Ground testing of flight spare components was conducted to determine the representative number and size distribution of particulate matter collected in flow tests [556]. For these tests and for filter qualification tests, a number of effects were examined. The influence of gravitational particle settling on ground test results versus the zero-gravity flight environment had to be considered.

The inlets to propellant valves are usually protected by filters to retain particles that might get lodged on the valve seat and cause the valve to leak when it is commanded shut. The screen material on the filters has to be compatible with the propellant, which in the case of IRFNA or NTO is a difficult task. The nitrate film growing on the thin metal wires might cause a narrowing of the passages and increase the pressure drop or embrittle the wires. Similar wire mesh is used in surface-tension PMDs in propellant tanks for zero-gravity operation. The long-term effects of propellant immersion on fine Micronic stainless steel wire cloth were studied for IRFNA and NTO and nine other propellants [557]. Immersion-time histories reported in the literature ranged from 3 months to 7 years.

7.5 Pumps for Dinitrogen Tetroxide Service

There are two types of pumps for NTO service: those on the launch vehicles and those in the ground service equipment (GSE) used to load propellant onto the launch vehicles. The difficulty is to find methods to lubricate the fast-rotating shafts. Conventional lubricants would react with NTO and constitute an explosive hazard. Pumps have been designed that are lubricated with the corrosive medium they are pumping, but minor irregularities (scraping blades) will cause ignition.

On 12 August 2003, at CCAFS launch pad LC-40 during the bleed-in operation for the TITAN-IV launch vehicle's second-stage propellant load, the oxidizer centrifugal pump exploded [553]. Along with the liquid N_2O_4 release of approximately 150 L (40 gallons), the explosion created a large amount of shrapnel that caused significant damage to the surrounding GSE. The pump was completely destroyed. Prior to the explosion, a reduced flow rate was noted while oxidizer was being loaded onto the first stage, and it was suspected that one of the filters became clogged with particulates. Following this event, all similar pumps at the Kennedy Space Center were replaced and surrounded by a shrapnel catch basket. There had been three other similar occurrences with oxidizer pumps in 1963, 1964, and 1980 throughout the history of the TITAN program.

Pumps, flow meters, valves, and pressure transducers for the TITAN-II missile were endurance-tested and calibrated in a closed-loop propellant pumping system containing two 22.7-m^3 (6000-gallon) tanks and two 984-L/min (260 gallons/min) pumps for NTO and Ae-50 [558].

A vacuum-tight electric drive was designed for a gear pump for pumped circulation of dinitrogen tetroxide [559]. The drive was designed for circulating dinitrogen tetroxide in a closed loop of a thermophysical high-pressure-flow test bench.

8 Handling of Dinitrogen Tetroxide

8.1 Handling and Ground-Service Equipment for Dinitrogen Tetroxide

The literature summaries listed in Table 46 provide useful information about the handling of N_2O_4 and other corrosive propellants. Most of these publications date back to the time in the early 1960s when TITAN-II missiles were under development and about to be placed in silos. Some of the publications deal with NTO as well as Aerozine-50 and other hypergolic propellants, so they are more of general industrial safety and historical interest.

Dinitrogen tetroxide is shipped as a liquid in steel cylinders and tank cars under its own vapor pressure (730 mm Hg [97 kPa] at 293 K [20 °C]). Dinitrogen tetroxide manufacturers will usually provide an instruction sheet with the shipment explaining how

to best transfer the propellant from the delivery vehicle into stationary storage installations.

Hypergolic propellants, NTO, and MMH can be handled safely if propellant-loading personnel are properly trained. A 2-day training course for safe handling of hypergols was developed and routinely held at NASA WSTF [571].

The design of hypergolic propellant GSE for fueling launch vehicles and satellites at NASA KSC is outlined in [572].

8.1.1 Long-term Storage Tests of Prepackaged Systems

Storable prepackaged propellant systems of a liquid rocket propellant feed system were designed, fabricated, tested, and delivered by General Dynamics Convair for subsequent use in a storability investigation by the Air Force Rocket Propulsion Labora-

tory (AFRPL) [573]. The propellant tanks were fabricated of Al-2219 and had a volume of approximately 57 L (15 gallons). Each of the 23 delivered systems consisted of a 15-gallon propellant tank that contained either a surface-tension force-orientation device or a rolling-diaphragm positive expulsion device, along with one of three different pressurization subsystems. The pressurization subsystems included a liquid propellant (hydrazine) gas generator, a solid propellant LFT-3 (AN composite) gas generator, or a stored gas device. Within the gas-storage bottle, 90% nitrogen/10% helium gas was contained at 20.79 MPa (3015 psia) by an explosive valve. Each tank was welded closed such that the propellant was contained within an all-metal, welded tank. Metal rupture discs, welded in the tank inlet and outlet, would rupture for propellant discharge when pressurized by the pressurization subsystem. The systems were delivered to AFRPL, hermetically sealed, and loaded with their respective propellants: mixed hydrazine fuel (MHF-5), dinitrogen tetroxide (N_2O_4), or chlorine pentafluoride (ClF_5). In addition, four tanks were delivered empty to AFRPL. One sample of each of the storage subsystems was test-fired shortly after being loaded with propellants, and the pressure history and propellant flow rate were recorded. This was to serve as a baseline for later comparison when the stored units were to be tested using the same procedure. This report described only the pre-storage testing. The test results of the multi-year stored units would be published later in separate reports.

During the first two phases of a four-phase metallurgical analysis of post-storage tanks, approximately 40 tanks storing NTO, ClF_5 or IRFNA had been examined after being stored at 303 K (+85 °F) and 85% relative humidity for up to 6 years. Under the first phase of this program, storage containers with N_2O_4 or ClF_5 , stored for periods of time up to and including 6 years of pressurized exposure, were examined and chemically and metallurgically analyzed [574, 575]. Tankage materials included aluminum alloys 2021, 2014, 2024, 2219, 6061, 7039, X7007, and 5456, as well as Arde 301 stainless steel, steel A-286, and Inconel 718. Two types of N_2O_4 , oxygenated and unoxxygenated, were evaluated for compatibility. The evaluation of the storage containers revealed that the major source of degradation was external due to a corrosive atmosphere in the storage shed. The primary cause of corrosion was the dilute-acid, high-humidity storage area environment. Internal corrosion observed in a very limited number of containers was attributable to a lack of thorough rinsing after exposure. The majority of internal surfaces showed little or no degradation from either oxidizer. Corrosion effects on the internal surfaces of aluminum and stainless steel tanks were negligible, with no serious degradation of strength or structural integrity occurring. Problems were seen only with some of the weldments in the manifolds through which the tanks had been filled and drained. For the most part, corrosion occurred on the outside of units where some leakage took place.

The third phase of the program involved the examination of a complete Bullpup missile containing IRFNA and MAF-1; see *Encyclopedia of Oxidizers*, chapter “Red Fuming Nitric Acid.”

During the fourth phase of the metallurgy evaluation program, 37–55-L (10–15-gallon) cylindrical steel A-286 and cryostretched spherical CRES-301 tanks with ring-stiffened reversing diaphragms for propellant expulsion that had been in long-term storage for 5–8 years at AFRPL, Edwards Air Force Base, and contained NTO or ClF_5 were examined for corrosion and leakage [576].

8.1.2 Transportation of Dinitrogen Tetroxide

Dinitrogen tetroxide is shipped under Hazard Classification 2.3, UN1067, with oxidizer, corrosive, and inhalation hazard warning placards.

The USAF buys, stores, and transports liquid dinitrogen tetroxide (N_2O_4) in support of the nation's military, NASA, and commercial space programs. Until 1999, the Air Force contracted with the Vicksburg Chemical Company in Vicksburg, Mississippi, for the manufacture of this oxidizer. Commercial carriers transported N_2O_4 to Air Force, NASA, defense contractor, and commercial test facilities throughout the country. The Vicksburg facility went through several bankruptcies, ownership changes, and name changes during the past decades and was eventually shut down. The next procurement cycle was with Mississippi Chemical Corporation in Yazzo City, Mississippi. In 2004, Mississippi Chemical Corporation was acquired by Terra Industries Inc. As of 2012, NTO was supplied by Terra Mississippi Chemical Company (formerly Mississippi Chemical Corporation, now CF Industries) in Yazzo City, Mississippi. It shipped NTO in bulk quantities by tank trailers and by rail cars. Smaller quantities were also transported in cylinders by truck and ship. The Defense Logistics Agency – Energy, Aerospace Energy business unit at Kelly Air Force Base in San Antonio, Texas, manages the procurement, transportation, storage, and disposal of this oxidizer and many other propellants for the Air Force. Shipments are made under the direction of the directorate's Transportation Office. This office initiates many safeguards to ensure that shipments are made in the safest manner possible and constantly looks for ways to improve the safety of the transportation system.

The Transportation Office also publishes Emergency Response Plans that provide guidelines for responding to highway and rail accidents or incidents involving N_2O_4 . The Department of Transportation (DOT) requires such a plan for moving this product in bulk on public highways and railways. The Air Force conducts training exercises in accordance with these plans. The greatest potential for spills or leaks is during coupling or uncoupling of the hoses for loading or unloading of tankers.

Routes for the transportation of N_2O_4 are selected using a computerized route-risk assessment program. The program computes a risk factor for each proposed route, considering such things as population, probability of an accident, and the potential effect an accidental product leak could have on the population along that particular route. The routes are reviewed periodically to meet DOT exemption and approval requirements. In response to protests from California lawmakers, the shipment route to

Vandenberg Air Force Base was changed. In 1990, a 200-page study by the Air Force evaluated alternate modes of shipping (rail, barge) but concluded that transportation by truck tank cars was still the best method. The study found that the USAF practice of trucking the fuel through southern California was preferable to shipping it by barge through the Panama Canal or transporting it by rail. The Air Force rerouted the shipments after elected officials from the San Gabriel Valley, the San Fernando Valley, and Ventura County protested against shipping it through their communities. A northern highway route through less-populated Barstow, Mojave, Gorman, Mariposa, and Santa Maria was selected instead.

The Air Force recognizes the risk in transporting N_2O_4 and has taken many precautions over the years to enhance the safety of product shipment. These precautions have proven effective. There have been no accidents resulting in the loss of liquid product on public highways in more than 30 years. As of 1978, the Space Fuels Logistics branch had shipped approximately 1.7 million pounds of NTO, 1 million pounds of MON-1, and 0.4 million pounds of MON-3 over 250000 round trip miles each year. Personnel in the USAF Logistics Directorate could remember only four incidents involving NTO trailers while in transit [577]. Only two of the four incidents resulted in the release of NO_2 vapors to the environment. There have been no reported incidents of leakage involving tank cars or one-ton containers while in transit. There have been problems with leaks at the quick disconnects while unloading at Vandenberg Air Force Base. Occasionally, rail cars being used for storage developed gas leaks in the dome area.

The Air Force contracts only with long-established commercial motor carriers who have excellent, industry-proven safety records. The experience, qualifications, and training required of drivers exceed Code of Federal Regulations requirements for drivers of other hazardous materials. Two drivers are assigned to each tank trailer carrying the product. Two tank trailers comprise a normal shipment.

Drivers receive formal training every 2 years on the physical and chemical characteristics of N_2O_4 . Training includes instruction on authorized routes of movement and safe stopping places; actions to take in the event of mechanical breakdown, accident or product loss; and other responsibilities such as required documentation and special shipping instructions. A trained technical escort team accompanies all shipments. The team provides an immediate emergency response capability and communications link to local and federal emergency response resources. All team members are thoroughly trained on the physical and chemical properties as well as the hazards of the propellant and the characteristics of the cargo tank trailer. They also receive hands-on training for minor repairs of the trailer. They receive training on hazardous material incident response that satisfies the U.S. Environmental Protection Agency (EPA) training requirements for those who first respond to the scene of such an incident. In addition, they receive classroom training on the Emergency Response Plan.

An accompanying truck carries the emergency response equipment and tools that may be used, if needed, by the team to mitigate minor product leaks or spills. This includes personal protective gear, tools and equipment, decontamination equipment

and supplies, and first-aid equipment and supplies. Although federal law does not require escorts for each shipment, an escort team accompanies each N_2O_4 tank trailer shipment.

8.1.2.1 N_2O_4 Tank Trailers

Special MC 338 tank trailers are used for the bulk highway shipment of N_2O_4 . The trailers are equipped with state-of-the-art safety features that far exceed industry standards and current federal packaging specifications for equipment used to transport products with similar hazards. The cargo tank trailers have the capacity to haul 9500 L (2500 gallons) of product.

The trailers and equipment are constructed from rugged stainless steel. The tank consists of an inner tank and an outer jacket. The annular space contains a gaseous nitrogen blanket to maintain an inert corrosion-free environment. A honey-combed material similar to aluminum at the front of the trailer is designed to absorb energy if the trailer is involved in a head-on collision, greatly reducing the possibility of a spill.

Valves and piping are located on the top rear portion of the trailer and are enclosed in a retractable steel cover and roll bars for protection. The roll bars can withstand the full weight of the trailer and its contents in a rollover without damage to piping or valves. Also, the cover will not close if any of the valves are not completely shut off. An additional safety feature is that each trailer has an emergency valve-leak kit of color-coded canisters specifically fitted for each valve. When installed, the canisters seal off any leaking valve until more permanent repairs can be made.

8.1.2.2 N_2O_4 Rail Shipments

Air Force shipments of bulk N_2O_4 by rail have been made to Cape Canaveral Air Station, Florida, and major users include the Aerojet Propulsion Systems Plant in California. At one time there were eight tank cars in the N_2O_4 rail fleet. The rail tank cars were built to class DOT 105J500W specifications. The tank cars were insulated stainless steel pressure cars, with a manway nozzle designed for top loading and unloading. Bottom outlets or washouts were prohibited. The tank cars were fabricated from SA-240, type 304L stainless steel. The tank car was equipped with thermal protection, full head puncture resistance shields, and double shelf couplers. The tank cars had the capacity to haul 37800 L (10000 gallons) of N_2O_4 . All valves and piping on these cars were located on the top, within a lockable dome, near the center of the car. A valve-leak kit of color-coded canisters was designed to specifically fit each valve. When installed, the canisters seal off any leaking valve until more permanent repairs can be made.

Until 1987, the USAF transported NTO under DOT Exemption DOT E-3121. In the fifth revision of DOT E-3121, the DOT placed several additional requirements upon the USAF as a requirement for reissuance of the exemption. The new requirements included an emergency response plan, risk assessments, updates for highway routes of movement, and periodic updates of the risk assessments to ensure that routes remain the safest possible.

8.1.2.3 Cylinders

With the end of the TITAN-III/IV program and then again with the end of the DELTA 2 program, the volume of NTO shipments decreased by orders of magnitude. For example, in 2012 DLA Energy Aerospace Energy shipped only 180 cylinders with N_2O_4 .

In July 2013, the DOT granted a 4-year extension to special permit DOT-SP 10497 (eleventh revision) to Lockheed Martin Commercial Space Systems for the transport of N_2O_4 in cylinders of 30-in diameter and 7-ft length [578]. In December 2013 a special permit (fourteenth revision) was issued for construction of modified 4BW stainless steel cylinders DOT-SP 11580 [579].

8.2 Design of Dinitrogen Tetroxide Storage Facilities

Stationary storage tanks should be under cover to be protected from rain and sun, but without side walls to allow good ventilation. Building structures should not contain combustible materials such as wood or tar paper. Corrugated aluminum sheeting is often used because it combines chemical resistance with good reflectivity in hot climates.

Storage and transfer installations should have a suction duct into which brown fumes from transfer and purging operations can be safely vented. Relief valves and burst discs from storage tanks can be connected to this line. It is recommended to keep a spare empty tank on standby into which the contents of a leaking tank can be transferred in case of an emergency. The report [567] contains a detailed layout for NTO storage areas and shows designs for NTO disposal facilities.

8.3 Transfer of Dinitrogen Tetroxide

The transfer of N_2O_4 between shipping and storage tanks on the ground can be achieved by pressurization, gravity, or pumps. Because tanks usually do not have a bottom drain for safety reasons, gravity transfer is not always possible. Most NTO tanks have a stand pipe (dip tube) to withdraw liquid from the bottom of the tank.

The vapor pressure of N_2O_4 at room temperature is not sufficient to enable transfer of the liquid through a stand pipe under its own vapor pressure. Transport and storage containers carry at least two ports through which the tank can be pressurized or depressurized, and a third port is connected to a stand pipe. If the propellant is transferred by pumps, one must feed dry, inert gas back into the tank that is being emptied, or one must connect a vapor return line that allows gas and vapors from the tank being filled to escape to the tank being emptied.

The choice between pressure transfer and pump transfer depends on the size of the tank. Pump transfer is usually employed only for large tanks.

Propellants for the second stage of the Delta launch vehicle were loaded from the pretreatment unit into the rocket by pressurized transfer [580]. TITAN-III and TITAN-IV launch vehicles were loaded with pumps.

8.3.1 NTO Propellant Transfer for In-Orbit Refueling

The Russian space program has had significant experience in transferring propellants (N_2O_4 and UDMH) between supply space ships and orbiting space stations, starting with MIR and continuing with the International Space Station.

The transfer of NTO and MON is more difficult than the transfer of storable liquid fuels like hydrazine, MMH, and UDMH. In the case of MON, each transfer operation results in loss of some NO, which changes the stress-corrosion behavior of the remaining liquid oxidizer.

In most cases, propellant transfer for in-orbit refueling has been practiced with other, less volatile fluids first before the zero-gravity transfer of NTO or MON was attempted. Transfer of cryogenic fluids would be even more difficult. See also [581].

8.3.2 Propellant Feed Systems for NTO in Rockets

The design of propellant feed systems in rockets, satellites, and space probes is a chapter in its own right. We are summarizing here only chemical properties of N_2O_4 that may influence the design of such systems. Only large rockets, such as space boosters in the size category of TITAN-III, TITAN-IV, and ARIANE-I through ARIANE-IV, DELTA upper stages, DNEPR, and PROTON will use turbopumps to feed the propellants into the combustion chamber. Satellite and space probe propulsion subsystems will typically use pressure-fed propellants.

The chemical considerations in designing feed systems include the compatibility, i.e., non-reactivity of the oxidizer with the pressurant gas. In selecting an inert pressurant gas, the reactivity and solubility of the pressurant gas must be known. Helium and nitrogen can be used as pressurant gases for N_2O_4 or MON. The solubility of pressurant gases in N_2O_4 and MON is summarized in Section 3.11 and 4.1.8.

There has been a considerable amount of concern about pressure surges when liquid propellants are entering a propellant distribution manifold that has previously been evacuated or filled with low-pressure gas. The “priming” of propellant feed systems may cause severe pressure spikes, even with chemically inert fluids. Priming with chemically reactive fluids such as anhydrous hydrazine may lead to explosions if extreme surge pressures are allowed. No such concern exists with NTO, so the main concern is about a strictly mechanical, fluid-dynamic event leading to pressure spikes. Studies have looked at both priming pressure spikes and water hammer pressure spikes in propellant feed lines. It is possible to develop an analogy between the classic water hammer phenomenon and the priming water hammer caused by surge flow. Several of the studies that were primarily concerned with priming

of hydrazine or MMH feed lines have also included NTO in their calculations and experiments.

Experimental test results with water in simplified straight and 90°-bent-line geometries were compared to numerical simulations computed for MON, MMH, or water using ANABEL software [582]. This computer program can perform the computation of transient compressible/uncompressible monophasic or diphasic flow with separated phases in fluidic networks, allowing the prediction of water hammer and also pressure losses. With a push pressure of 40 bar, the predicted pressure spikes at the end of the line were 200 bar for MON, 172 bar for MMH, and 183 bar for water.

Fluid hammer experiments were conducted with NTO, MMH, or water in the propulsion laboratory of Office National d'Etudes et de Recherches Aérospatiales (ONERA) [583]. The objective of that study was to generate a reliable experimental database on the fluid hammer phenomenon with real propellants (NTO and MMH) to validate the physical models implemented in the numerical codes. Only one experiment was performed with NTO for a vacuum pipe pressure below the saturation pressure. Compared to MMH and water experiments performed under the same operating conditions, the fluid hammer amplitude and frequency with NTO were smaller. Regarding the peak temperature in the gas pocket, very small variations were recorded for water and MMH, whereas the temperature increase for NTO was more than 623 K (350 °C).

8.4 Decontamination of Dinitrogen Tetroxide Tanks

8.4.1 Decommissioning of N_2O_4 Systems

In the wake of and at the end of the Cold War, numerous missile launch silos containing storable hypergolic propellants had to be decommissioned and neutralized on both sides of the Iron Curtain.

The United States entered into the SALT-II agreement with the Commonwealth of Independent States (the successor to the USSR) to assist them in the removal and safeguarding of missiles and their payloads. Several conferences were held to exchange information on the decommissioning of the missiles and disposal of the propellants. In addition to NTO (code name Amyl), large quantities of RFNA (code name Melanj) had to be destroyed. In the evaluation of various disposal methods, methods were sought that would result in useful products, such as fertilizer.

Most hypergolic bipropellant engines undergo an acceptance test firing at the manufacturer's facility before they are mounted on a flight system. Subsequent to the acceptance test firing, the engines have to be thoroughly decontaminated. Decontamination methods differ for ground test equipment and flight systems. For flight systems, it would be best to fill them with propellants only once, immediately prior to launch. In some unforeseen circumstances, the launch may be postponed, and in those cases propellants have to be drained for storage or repair of the spacecraft. Dinitrogen tetrox-

ide, NTO, or MON is difficult to remove from ground test equipment or flight systems because even after all of the N_2O_4 evaporates, a thin film of nitric acid residues is left on the equipment, which may still be quite corrosive if not immediately removed.

In order to decommission a missile or a rocket test stand containing NTO, the first step is to drain the tanks and lines of liquid N_2O_4 , followed by a purge with hot, dry nitrogen [347]. After the purge gas is free from NO_2 , there usually remains a thin film of nitric acid and other less volatile or non-volatile residues on the tank walls. The complete removal of these residues can be achieved by rinsing with a dilute solution of triethanolamine, a method that was widely used for the cleaning of Titan-II engines [584].

8.4.1.1 Evaluation of N_2O_4 Equipment Decontamination Methods

Decontaminating a propulsion subsystem by pressure cycling by filling the tanks with nitrogen up to the maximum expected operating pressure (MEOP), allowing equilibration with the vapors, preferably at moderately elevated temperatures, and repeating this process many times may have advantages over solvent flushing. It was a serious error that continued use of methanol and Freon MF was recommended for decontaminating Apollo service module propellant tanks in spite of some concerns expressed by other metallurgists.

During the Apollo service module and lunar module development, the use of improper solvents (methanol) resulted in unexpected failure of an NTO tank. Subsequently improved methods were sought for propulsion subsystem decontamination that avoided the use of methanol. The compatibility of solvents with propellant and components was evaluated in a series of laboratory studies [585–587]. In addition, the methods for decontamination, sequence of solvents used, temperature dependence of solvent efficiency, diffusion rate of absorbed propellant from elastomers, removal of propellant from flushing solvents, and disposal of propellant-contaminated flushing solvents were studied. Even after all of the N_2O_4 is removed from a tank, the next question is how to remove the residual flushing solvent. Since the tanks cannot be evacuated because they would collapse, an extended dry inert gas (nitrogen) purge would be required to remove all solvent before the tank is put into storage or used again with a fresh load of propellant. Small spacecraft or propulsion subsystems could be placed into a vacuum chamber and vacuum applied to both sides of the tank to encourage residual solvents to evaporate.

There have been at least two incidents during which MON had to be downloaded from a spacecraft. The launch of Galileo was postponed in 1986. Because of safety concerns after the Challenger accident, NASA cancelled the planned use of the CENTAUR on the Space Shuttle, and Galileo was moved to the two-stage interim upper stage (IUS), later launched in October 1989 on STS-34.

The other incident happened in 2008 when an Orbital Sciences satellite on a STAR-2 platform had to be destacked from the launch vehicle because, a few days prior to the scheduled launch in Baikonur, a clumsy crane operator had accidentally bumped into

the antenna of the satellite and damaged it beyond on-site repair [588]. The satellite had to be destacked, off-loaded, and decontaminated before it could be flown back to the manufacturer's facility in the United States for antenna replacement. It took substantially longer to fully inert the hydrazine fuel tank than it took to inert the MON-3 oxidizer tank. All of the previous off-loading incidents had involved MMH instead of N_2H_4 as the fuel, which is more volatile and easier to remove than N_2H_4 .

The ROSETTA space probe was originally fueled in November 2002 and scheduled for January 2003, but after a failure of an ARIANE-5 launch vehicle on an earlier mission, the launch had to be postponed, and the MMH was off-loaded but the MON was not. Although the MON tank was neither off-loaded nor depressurized, it is interesting to follow the logic in the decision not to off-load the MON tank [469, 589–591].

8.5 Atmospheric Dispersion of NO_2 Fumes in Case of Accidental Releases

Of all rocket propellants flying at this time, the concern about toxicity effects of accidental spills is the highest with NTO and MON. The boiling point of these oxidizers is close to room temperature, the vapor pressure is close to atmospheric pressure, and the vapors are heavier than air, slowing down their dispersal. There are many computer models for predicting atmospheric dispersion of toxic chemical vapors under a variety of source strength and atmospheric conditions [592–594] and the modeling of an NTO spill is typically run as a test case because there are some real-life dispersion test data available to compare the accuracy of the model to. Most of the plume models are for emissions from stationary sources such as power plants, where the hot stack gases are buoyant and disperse more quickly than a spill of a vaporizing liquid at ground level. These models produce an elapsed-time-resolved three-dimensional map of the plume downwind of the spill site, compare it to the recommended maximum-allowable exposure limit for the general public, and determine the need to evacuate the population from the affected area. Some of the models allow for chemical interaction of spilled chemicals with atmospheric oxygen and moisture, as would be the case with spilled N_2O_4 or N_2H_4 .

One of the models widely used by the USAF during the time when most N_2O_4 was transported to and from TITAN launch sites was AFTOX, which was easy to run on a personal computer [595, 596]. AFTOX is a Gaussian puff dispersion model for uniform terrain and wind conditions. It can handle continuous or instantaneous releases, liquid or gas, and elevated or surface releases from a point or area source. AFTOX 14.0 represents an upgraded version based on comments from users after operating the model for 2 years in the field. The changes made the program more user-friendly and improved it technically.

Other models cover different spill-site geometries and atmospheric conditions to calculate toxic vapor corridors downwind or downhill from spill sites [597–599]. Reac-

tions of the chemicals, if any, with water vapor in the air are modeled and considered in some of the dispersion models [600]. Several other atmospheric dispersion models have been applied to modeling accidental NTO releases in the atmosphere.

Field diffusion tests were conducted at Cape Canaveral in Florida and Vandenberg Air Force Base in California during 1961 and 1962. These programs, nicknamed Ocean Breeze and Dry Gulch, respectively, were undertaken to establish quantitative diffusion predictions for use as range safety tools at the missile test ranges [601]. The programs culminated at each range with the installation of an automatic computer-controlled meteorological data acquisition and processing system for continuous operation at the bases.

A vapor cloud caused by either vaporization or reaction of hydrazine, UDMH, MMH, and NTO, as it was used on the Apollo spacecraft, was analyzed to determine the generation and concentration of toxic products and the safe toxic distances in case of a spill [602]. It was predicted that the process of vaporization of propellant without reaction creates the largest quantity of toxic products. Assuming that the total quantity of fuel or oxidizer aboard the APOLLO spacecraft would be spilled in sand and vaporized during unfavorable atmospheric conditions, it would have resulted in a maximum safe toxic distance of 5.5 km (3.4 miles). This safe toxic distance was considered to be the worst case, as the cooling effects of vaporization tend to reduce the actual rate of vaporization. Reaction of hydrazine, UDMH, or MMH with NTO will produce a smaller quantity of toxic products, thus reducing the toxicity hazard. When formed, these hot products, being above ambient temperature and buoyant, will rise and expand, creating a faster rate of product dilution.

SURFACE CHEMKIN is a widely available computer program developed for kinetic modeling of chemical vapor deposition that can be adapted for kinetic modeling of multi-phase chemistry in the atmosphere, such as vapor dispersion and absorption from an NTO spill [603, 604]. It can deal with multiple phases having different reaction paths in each phase. It can deal with gas, surface, and bulk reactions and mass transfer rates; it keeps track of the phase equilibria with realistic activities; and it can operate in an adiabatic mode to include the effect of heat release on the system. When applied to the problem of a dinitrogen tetroxide spill in the troposphere, the model is able to predict the formation of a nitric acid/water aerosol and follow the chemistry taking place in both the gas and liquid phases as the spill dilutes in the surrounding atmosphere. The model predicts that in such a spill, most (70–90%) of the nitrogen oxides released are converted to nitric acid over a wide range of relative humidity atmospheric conditions. The launch-abort problem is especially difficult because there are separate initial clouds of fuel and oxidizer, with regions of mixing between them. One way to deal with this problem is a “multi-bin” approach that treats the fuel and oxidizer and an interface as separate bins but keeps the computation tractable [605]. The model results showed that the outcome is highly dependent on initial conditions. A likely scenario for a Titan IV launch mishap may result in 24% of the initial oxi-

dizer remaining, of which at least half is transformed into nitric acid after reacting with atmospheric moisture, and with 2% of the initial fuel remaining. Heterogeneous chemistry modeling showed that half of the released N_2O_4 will convert to HNO_3 .

A mathematical model was developed to predict propellant vapor clouds released from a theoretical explosion involving a Titan II, Delta II, or Titan IV launch vehicle [606, 607]. The model was based on a variety of scientific and engineering input: the chemical description of interacting rocket propellants, data from previous accidents involving these or similar launch systems, an analysis of vehicle failure modes and propellant mixing characteristics, and thermochemical properties of reacting rocket propellants and their combustion products. Outputs of the model included the chemical composition and average molecular weight of the fireball cloud, the adiabatic flame temperature, the fireball size, and the total heat release. Required input variables to the model were time and altitude of the explosion, the mixing ratio for liquid propellants, amounts of unreacted liquid rocket propellants thermally decomposed, and the amount of air entrained into the fireball cloud. The mathematical model has been encoded into Fortran 77 for integration with the rocket exhaust effluent diffusion model once used at the Vandenberg Air Force Base space launch complex.

A photo of a dramatic launch-abort of a Titan-34D at Vandenberg Air Force Base in April 1986 showed brown clouds of evaporating NTO on top of a shower of burning chunks of solid propellant falling from the two destroyed strap-on boosters [608]. The self-destruct mechanism had to be activated by the range safety officer by remote command after irregularities in one of the two solid propellant strap-on boosters had been detected. It would have been interesting to have taken more photos of the rate of dispersion of the reddish-brown cloud and compared it to predictions of some of the computer models.

Predictions of a model of evaporation characteristics of N_2O_4 and UDMH propellant in the air were in good agreement with experimental results simulating a launch-abort of a Long March launch vehicle [609–612]. A different model was developed for evaporation of NTO from a stagnant pool of a contained open-air spill [613]. In this case, the experiment was designed by simulating the evaporation environment of NTO leaking to form a liquid pool in a storage area. The variables such as wind speed, liquid pool area, temperature, and humidity that affect the evaporation rate of NTO were studied. The results showed that the evaporation rate of NTO correspondingly increased with the increase of any one of these factors. A model of NTO evaporation was established to predict the evaporation rate under storage conditions. The experimental results provided reliable data for research on safe treatment and personal protection related to the harmful gas environment formed after NTO propellant leakage during storage.

If upper stages vent unused NTO after stage or payload separation and while coasting prior to reentry, or if they explode because of aerodynamic heating during reentry, large amounts of residual N_2O_4 and NO_2 may be released into the upper stratosphere

and interfere with the ozone layer [614]. The influence of dinitrogen tetroxide on the ozone layer was described by a quasi-three-dimensional model that described the processes of diffusion and of the ozone photochemical interaction with the admixture. Results of model calculations were presented for release points at altitudes of 25, 30, 35, 40, and 45 km in the atmosphere. After launch, first-stage boosters cease operation at altitudes of 40–60 km; after that, they separate and fall to the ground. During the descent the propellant tanks of the first stage are usually destroyed, and remnants of the propellants splash onto the soil. Second stages cease operation at altitudes of 150–300 km. The second stages then separate and, moving along a ballistic curve, enter the dense layers of the atmosphere with a high velocity and are destroyed at altitudes of 20–50 km, i.e., inside the atmospheric ozone layer. The model simulations demonstrated that the ozone in the NO_x cloud center would be destroyed during 2–3 s at all heights. Since the ozone reaction with nitrogen dioxide formed in the process of dinitrogen tetroxide dissociation is very slow, the primary process is the nitrogen dioxide photodissociation, and then the formed nitric oxide reacts with the ozone. The ozone photodissociation is by orders of magnitude a weaker source of oxygen atoms than the nitrogen dioxide photodissociation. Model calculations were made for the total ozone depletion under a release of 1000 kg of dinitrogen tetroxide at various heights. The estimates demonstrated that a local release of large quantities (1000 kg) of the ozonoactive nitrogen oxides as the result of destruction of a rocket's second stage in the atmosphere should not lead to a long-term, large-scale depletion of the total ozone. One must understand that typically about 1300 kg of nitric oxide are released into the ozonosphere (20–50 km) together with the normal exhaust of the rocket's first-stage propellant combustion (e.g., for a Proton rocket), which corresponds to about 2000 kg of nitrogen dioxide. Thus, the release of the propellant remnants in the process of a rocket's second-stage destruction are comparable to the amount of nitrogen oxides thrown into the atmosphere each time with the normal products of combustion. In addition, simultaneous release of excess oxidizer and excess fuel, often from hypergolic combinations, may start a fireball and accelerate the consumption of residuals in the atmosphere or on impact on the ground.

Residual liquid propellant that is sprayed into the atmosphere at high altitudes and low ambient pressure may result in propellant droplets instantly freezing from sudden evaporative cooling and falling greater distances before they are warmed and evaporated [615].

8.6 Venting and Passivation of Propulsion Subsystems in Space

Explosions and fragmentations of spent upper stages or decommissioned satellites in space have been blamed on residual propellants and have created clouds of orbital debris. International space policies now require that upper stages and satellites be emptied of all residual propellants and be passivated at end of life.

A numerical study was performed to evaluate the Ariane 5 third-stage inerting by separately venting NTO and MMH third-stage tanks to vacuum after the deployment of payloads and prior to reentry. Two-dimensional viscous flow calculations were performed through the venting nozzles, and two-dimensional simulations were used from the nozzle exit conditions to determine the plume characteristics [616, 617]. The flow-rate decay with decreasing feed pressure was analyzed, and correlations were proposed to describe the plume spatial and temporal distribution. The solid-liquid-vapor phase diagrams of NTO and MMH were required for the analysis, and equilibrium phase changes were examined. It was concluded that the gaseous species produced by the venting process will not condense on surfaces warmer than 250 K. The phase-change assessment requires further non-equilibrium condensation analysis, with experimental validation.

Venting surplus NTO or MON in space will create a cloud of frozen N_2O_4 crystals [618, 619]. The particle size of the N_2O_4 snow was determined by Rayleigh light scattering observation conditions. The light source was an Argon laser emitting a 5-mm-diameter beam normal to the direction of flow. It was deduced that condensation occurred inside the nozzle, and the size of the largely sub-micron-size particles increased with the distance from the throat.

Similar venting tests and thermodynamic calculations have been performed for venting hydrazine from upper stages. Hydrazine behaves similarly to water, and it might form chunks of frozen hydrazine that would clog the pipes or adhere to the spacecraft. There is less concern about clogging fuel lines when venting MMH or UDMH because they have lower freezing points than hydrazine or NTO.

Part of any dinitrogen tetroxide that has leaked into the vacuum of outer space will freeze and may cluster around the leak site. The frozen dinitrogen tetroxide will slowly melt and sublime [620].

8.7 Controlled Spill Tests with Dinitrogen Tetroxide

As part of the TITAN-II development program, the USAF performed controlled deliberate spill tests with both N_2O_4 and Aerozine-50 to simulate a worst-case scenario [621]. A series of tests was performed to determine the potential hazards of TITAN-II propellant handling mishaps. Twenty model missile spills using total propellant quantities of 22.7 and 136 kg (50 and 300 lbm) and two large-scale spills using total propellant quantities up to 726 kg (1600 lbm) were made at Haystack Butte, Edwards Air Force Base. The TITAN-II propellants, NTO and Aerozine-50, were also spilled in quantities up to 1.13 kg (2.5 lbm) of total propellant in a series of small-scale tests conducted at the Propulsion Field Laboratory. A biological survival field study was performed on one large-scale test at Haystack Butte.

While most of the other spill tests and computer model predictions dealt with spills of only one TITAN-II propellant at a time, conditions of a simultaneous spill

of both components were modeled only after an accident in one of the Titan-II silos destroyed the missile and caused a fatality [622]. In 1980, a TITAN II accident occurred near Damascus, Arkansas, in which the scenario was much different from the one for which the toxic hazard corridor plume dispersion calculation procedures had been developed. Leaking fuel within the silo eventually made contact with the oxidizer on board a TITAN-II, leading to a violent explosion that sent combustion products and possibly some unreacted propellant several thousand feet in the air, where the atmospheric dispersion process began. The model was designed to characterize the interactions of hypergolic liquid rocket propellants and to provide information pertinent to the development of a model that would describe the transport and diffusion process of the airborne combustion products and unreacted propellant vapors resulting from a catastrophic accident involving hypergolic liquid rocket propellants burning either in the open or in the confined space of an underground silo. The internal pressure required to lift the heavy silo lid and the TNT equivalence of the NTO/Ae-50 reaction were calculated. Volume 2 of the final report discussed the chemical and physical interactions of the combustion products with ambient air [623]. The atmospheric dispersion of the products was described by considering the coupled effects of convection, dispersion, and chemical reaction.

The measured source strength and downwind dispersion results of two controlled N_2O_4 spill tests were used to evaluate four different source strength and dispersion models [624]. One conclusion from these source strength comparisons was that the internal energy (evaporative cooling) heat source is a major contributor to the source strength.

Two field-scale releases of dinitrogen tetroxide were performed at Lawrence Livermore National Laboratory for the USAF as part of the Eagle series. Data gathered during this experiment were fitted to a computer atmospheric dispersion model, and corrections for interaction of $\text{N}_2\text{O}_4/\text{NO}_2$ with ambient humidity and oxygen were applied [625]. The reported source rate for one experiment was 2.9–3.4 kg/s, while the source rate for the other experiment was 1.6–1.9 kg/s. Reported NO_2 concentrations downwind of the source were corrected for the mass evolution rate, and these observed concentrations were compared with predicted concentrations using the Ocean Breeze/Dry Gulch model.

At a time when the TITAN II missiles were being decommissioned, resulting in an increase in the overland transportation of N_2O_4 , a series of instrumented, controlled large-scale spills of 3–5 m^3 of N_2O_4 were performed at the Nevada test site for the Air Force Engineering and Services Laboratory, Environics Division [626, 627].

Large-scale, extensively instrumented controlled spill tests of liquid ammonia and liquid dinitrogen tetroxide were performed at the Nevada test site, resulting in large amounts of data that can be used to quantitatively describe the observed phenomena [628]. Preliminary results from both test series indicated that aerosols played a very important role in dense gas dispersion. The test data were ideally suited

for model validation. Gaussian model calculations were found to be inadequate even at long distances downwind.

A series of large-scale dinitrogen tetroxide spill tests were conducted to determine the source strength characteristics and heavy-gas dispersion aspects of large N_2O_4 spills. The source strength and downwind dispersion results of two of the spills were used to evaluate several source strength and Gaussian dispersion models [629, 630]. It was concluded that the internal energy heat source is a major contributor to the source strength, that source strength models need improvement, that formation of a dense HNO_3 mist may account for much of the downwind mass transport of large N_2O_4 spills, and that all models evaluated underpredicted downwind gas concentrations. The purpose of these experiments was to study the evaporation rates and heavy gas-dispersion aspects of realistic size releases of N_2O_4 . Some typical results for one of the spills included the atmospheric boundary layer conditions in effect during the spill, the spill area heat flux and vapor temperature, the vapor flux measured at 25 m downwind, and the NO_2 gas concentration contours at 785 m. The measured NO_2 concentrations were compared to those calculated with the Air Force Ocean Breeze/Dry Gulch model.

Measured results from a total of 26 benchmark spill tests were chosen from the Lawrence Livermore National Laboratory Burro (LNG), Coyote (LNG), Desert Tortoise (ammonia), and Eagle (nitrogen tetroxide) tests; the Shell Research Maplin Sands tests (LNG and LPG); and the British Health and Safety Executive Thorney Island test (Freon-air mixtures) and were compared to model predictions [631]. Only continuous finite duration releases were selected for the test summaries because they were considered to better represent typical accidental releases from a storage vessel or transportation vehicle. The test summaries described the manner of release, the ambient meteorological conditions, and the resulting vapor cloud characteristics, including peak concentration, average centerline concentration, and average height and width of the cloud, all as functions of downwind distance.

8.8 Disposal and Spill Cleanup of Dinitrogen Tetroxide

Disposal and spill cleanup of dinitrogen tetroxide has been practiced for many decades, and there exists a good database on available methods for safe handling of this oxidizer, e.g., Chapter 3 in [632].

8.8.1 Absorption, Scrubbing, Neutralization, and Disposal of Vented Nitrogen Dioxide

If large quantities of N_2O_4 have to be disposed of, the choice is between wet absorption or combustion in a flare stack or solid absorbents in a canister. This problem usually occurs with the NO_2 -laden pressurant gases that are vented from storage, transport,

or run tanks when the liquid is transferred by pressurization instead of mechanical pumps. The *Hypergolic Propellants Handbook* contains an evaluation of various techniques for the destruction of NO₂ in vent gases from pressurized NTO tanks [561, 632]. The most economical method would seem to be to dissolve the vapors in aerated water, resulting in a dilute solution of nitric acid and nitrous acid. The acid solution then would have to be neutralized with caustic lime slurry before it could be released or sent to other applications. However, nitrogen dioxide dissolves only very slowly in water.

8.8.1.1 NO₂ Absorption with Wet Scrubbers

The problem with wet scrubbers is that NO₂ fumes do not dissolve in water very readily, and the reaction

takes a long time to go to completion [558, 633]. This reaction is part of the commercial process for production of nitric acid. The absorption rate of nitrogen dioxide-dinitrogen tetroxide gas mixtures from nitrogen into water plays an important role in industrial production of nitric acid and removal of NO₂ from gaseous mixtures. The results of a study of the mechanism of NO₂ absorption in a wetted wall, falling film column agreed well with known absorption mechanisms, and additional data were obtained on the liquid-side kinetics of this absorption process [634].

Instead of using plain water, a more effective method is to absorb the vapors in an aqueous solution of sodium hydroxide and sodium sulfite, where the sodium sulfite acts as a reducing agent. But such absorption towers/vapor scrubbers create a large volume of spent solutions that then need to be disposed of at substantial expense [635].

Experiments were conducted on a model wet scrubber in order to verify and rank the performances of several candidate scrubbing liquors. The most efficient scrubbing liquor found experimentally was a 10% sodium sulfite solution [636]. This was in agreement with a previous study by Exxon performed under a U.S. EPA contract. Other scrubbing solutions tested have been potassium permanganate (KMnO₄), ozone (O₃), sodium hydroxide (without sulfite), sodium hypochlorite, urea, triethanolamine, ammonia, and hydrogen peroxide (H₂O₂) solutions.

Pressurant gases vented from NTO/MON tanks were usually scrubbed with a sodium hydroxide/sodium sulfite solution, resulting in a hazardous liquid waste. As an environmentally more friendly alternative, the use of a solution of potassium hydroxide and hydrogen peroxide for the NTO/MON vent gas scrubber system was investigated [637]. The potassium nitrate solution formed could be potentially used as an agricultural fertilizer instead of having to be disposed of as a hazardous waste. The hydrogen peroxide was added to convert the potassium nitrite that was initially formed into the more useful and less toxic potassium nitrate. Small-scale laboratory tests were conducted to establish the storage stability of hydrogen peroxide in the

proposed scrubbing solution and to evaluate the effectiveness of hydrogen peroxide in converting nitrite to nitrate.

In order to find a more efficient method to reduce nitrogen oxide pollution when venting pressurized oxidizer tanks during propellant transfer or ground testing of rocket engines, pressurized absorption was studied with simulated waste gas [638]. The results showed that at lower pressures (0.1–0.4 MPa), the nitrogen oxides' absorption efficiency in water decreased with increases of the inlet concentration of nitrogen oxides, but at higher pressure (0.4–0.8 MPa) it increased with increases of the inlet concentration. The absorption efficiency increased with increases in the operation pressure, and the efficiency at 0.8 MPa was six times greater than that at atmospheric pressure, but the increase was less significant with pressures higher than 0.6 MPa. The optimum pressure was 0.4–0.6 MPa. The operating cost of pressurizing gas disposal can be compensated by the nitric acid recovery if a commercial use can be found for the dilute acid.

Nitric acid factories have designed special absorption towers to achieve dilute nitric acid, which subsequently has to be concentrated to obtain a commercial product. For a rocket test-stand waste-gas neutralization installation, one can use caustic (20% NaOH) solution instead of water in order to speed up the gas absorption process [639].

It was generally assumed in the past that the reactions between nitrogen dioxide and water occur by a mechanism in which gaseous nitrogen dioxide diffused into the liquid phase, where the chemical reactions take place. It was suggested that a gas-phase reaction may occur, and other investigations indicated that the gas-phase reaction may be of considerable importance in the overall reaction mechanism. To design efficient equipment for aqueous absorption of nitrogen dioxide, it is necessary to know whether the important chemical reactions occur in the gas phase or in the liquid phase. Other studies indicated that the rate of aqueous absorption of nitrogen dioxide is controlled by the rate of the chemical reaction rather than by diffusion. Therefore, by the use of chemical kinetics, it should be possible to predict the manner in which the concentration of the reactants affects the rate of nitrogen dioxide absorption. The chemical reaction of importance may be expressed by

These equations represent the reaction rate constants for the forward and reverse reactions. Reactions 1, 2, and 5 occur simultaneously, while reactions 3 and 4 are con-

secutive to reaction 1 and 2. The oxidation of nitric oxide (NO) to yield nitrogen dioxide (NO_2) and dinitrogen tetroxide (N_2O_4) proceeds at a relatively slow rate. This reaction is not included here because experimental tests with a wetted-wall column indicated that the rate of nitric oxide oxidation was too slow to have any appreciable effect on the results. Even after all of the NO_2 is absorbed, there is still the question of how to dispose of the resulting solution containing sodium or calcium nitrite and nitrate.

For stationary installations used to neutralize the fumes after venting pressurized NTO tanks, spray nozzles can be arranged in such a way that they act like an aspirator and entrain the fumes or the vent gases from a tank that need to be neutralized. The caustic solution can be recirculated until it is saturated with nitrate and nitrite.

Hypergolic oxidizer and fuel pressurant gases are (were) vented during fueling and deservicing of the Space Shuttle and other spacecraft, which were cleansed of toxic propellant vapors before allowed to be vented to the environment. The scrubbers were not 100% efficient, and traces of propellant vapors may have passed through the apparatus. The environmental protection agencies wanted to know how much propellant vapor escaped entrapment. Scrubber emissions are difficult to measure due to the intermittent purge flow and the presence of suspended scrubber liquor droplets. An alternative method for emissions monitoring was introduced [640]. It was suggested that emissions can be determined from field scrubbers without direct measurement of vent flow rates and escaped hypergol vapor concentrations. This alternative approach was based on the scrubber efficiency, which had been previously measured during normal steady-state operations, and on the accumulated weight of hypergol captured in the scrubber liquor, which is part of the routine monitoring data of scrubber liquors. The emissions from scrubbers can be calculated by measuring the buildup of hypergol propellant in the liquor and then using the appropriate efficiency to calculate the fugitive emissions. An estimate of the total emissions from 16 scrubbers at NASA KSC indicated that 0.3 kg/year of fuel (MMH and hydrazine) and 234 kg/year of nitrogen dioxide were emitted [641].

It has been proposed to convert the NO_2 scrubber liquors to nitrate fertilizer that has commercial agricultural value. Used, unwanted scrubbing liquor consisting of an equimolar mixture of nitrate and nitrite dissolved in a highly alkaline solution (pH 13) was usually disposed of as hazardous waste. However, this waste liquor can be converted into nitrate fertilizer by oxidizing the nitrite to nitrate with ozone and neutralizing the alkali with nitric acid to form a nitrate solution at pH 7 [642–645]. The NO_2 scrubber liquor starts with 1% hydrogen peroxide at a pH of 7 in the first zone, and the process control system adds hydrogen peroxide and potassium hydroxide to the scrubber liquor in a second zone to maintain the initial pH and a slight excess of H_2O_2 . The result is the formation of a solution of potassium nitrate, which is sold as a fertilizer. This report describes the equipment and procedures used to monitor and control the conversion of the scrubber liquor to fertilizer, while at the same time reducing the scrubber emissions.

Hypergolic oxidizer used at most launch facilities is not pure N_2O_4 but is rather MON-1 or MON-3 with varying amounts of N_2O_3 added in the form of NO. The vapor phase above MON contains more NO than the liquid, and when vented, the NO is released first and may pass through the scrubber unchanged unless it has a chance to react with an excess of air to convert itself to NO_2 . The conversion of NO to NO_2 can be accelerated by UV illumination of gases entering the air-filled scrubber [646].

8.8.1.2 NO_2 Absorption into Dry Chemical Absorbents

A dry-chemistry $\text{NO}_2/\text{N}_2\text{O}_4$ disposal system without the need to pump and recirculate liquid absorbent solutions through an absorption tower would destroy the gaseous $\text{NO}_2/\text{N}_2\text{O}_4$ mixture by passing it over a hot bed of charcoal, coal, or coke, where the oxides of nitrogen would be reduced to nitrogen gas and CO/CO_2 [647]. If there is concern about the poisonous CO, it can be converted to CO_2 by adding more air and passing it over a heated copper oxide catalyst before releasing it above the roof.

8.8.1.3 NO_2 Condensation for Recycling

If NO_2 in vented pressurant gases has to be removed on a regular basis rather than only on an occasional basis, it may be more economical to collect the NO_2 by condensation in a cold trap in the form of N_2O_4 and recycle it [648]. Theoretical calculation results of the condensation recovery rate and the required cooling power of an engineering development unit showed that condensation recovery of N_2O_4 in the waste gas is feasible and profitable in engineering applications. A simulation computation model was performed by using HYSYS and condensate-recovery process flow charts. The test results of an engineering development apparatus based on these parameters at Jiuquan Satellite Launch Center indicated that the recovery efficiency can be greater than 90%, and the purity of N_2O_4 recovered can be up to 99.6%.

8.8.2 NO_x Vent Gas Scrubbers

Each time an NTO oxidizer tank in a stationary installation or in a reusable space transport returning from orbit has to be depressurized, the pressurant gas is saturated with $\text{N}_2\text{O}_4/\text{NO}_2$ and carries substantial amounts of toxic fumes that in most installations cannot be simply vented to the atmosphere. In the case of the Space Shuttle, the amount of vented NO_2 during loading was between 2 and 6 kg (4.5 and 14 lb_m) of NO_2 for the OMS and RCS tanks [649]. The vent gases are usually passed into a scrubber with an aqueous absorbing solution that is recirculated until it becomes saturated with NO_x . Although this can be done with plain water, various absorbing solutions have been tested that not only absorb NO_x but also neutralize it at the same time.

Solutions of sodium carbonate, sodium dichromate, or potassium permanganate have been evaluated as scrubber liquors for the absorption and neutralization of nitrogen dioxide [650].

A scrubber built by MMC for NASA Kennedy Space Center to NASA Kennedy Space Center design specifications consisted of four in series packed-bed (ceramic saddle) scrubbers with a common sump tank [651, 652]. Initially, testing was done with 2–8% NaOH solution. The desired output of 150 ppm NO_2 or less was not obtained with the 2–8% NaOH sump liquor. Several possibilities were investigated to evaluate whether the scrubber towers were flooding at certain test conditions or whether the gas was channeling in the towers so that maximum scrubbing would not be achieved. Subsequent tests were performed with 10 and 25% Na_2SO_3 solutions, which worked much better, and the exit gas concentration was below 150 ppm NO_2 . A mixture of 5% NaOH and 18% Na_2SO_3 in water was recommended as the sump liquor to be used in the oxidizer scrubber. An analysis of the test data from this system tried to normalize the operating conditions to identify the variables (gas flow rates, liquor flow rates, liquor composition and concentration, NO_2 inlet concentration, level of exhaustion of absorption capacity) that had the most impact on the performance of the system [653].

Part of the initial problem with using the wet scrubbers on vented hypergolic propellants was the ultimate disposal of the liquid scrubber wastes after the liquor absorption capacity was exhausted. Consideration was given to all possible methods of reducing the amounts of chemically bound nitrogen in the wastes to stay within the guidelines established by the state and federal agencies. These guidelines require that the total chemically bound nitrogen discharged to any body of water be no more than 5.0 ppm. One proposed method was the use of water hyacinths in open-air disposal ponds to reduce the waste concentration in the effluent to acceptable levels [635].

The scrubber used at DELTA second-stage fueling installations at Cape Canaveral Air Force Station and Vandenberg Air Force Base used a two-stage scrubber design using 5% sodium bicarbonate solution as a vapor-neutralizer scrubber liquor [580]. Design specifications were that the scrubber should be capable of reducing 115030 ppm NO_2 to 500 ppm from 400 scfm for 15 min.

Pilot-scale experiments of a packed-bed scrubber were conducted to investigate the effects of seven design and operating parameters on the removal of NO, NO_2 , and N_2O_4 from a nitrogen vent gas stream venting from an NTO/MON tank [654]. This was done to obtain design guidelines and scaling criteria for the design of a full-size caustic scrubber for a launch installation. The scaling criteria were in the form of a computer model that could be tweaked to obtain the optimum operating conditions. The reactions of NO, NO_2 , and N_2O_4 with a dilute NaOH solution with and without added air were analyzed. It was attempted to improve the performance of alkaline NO_x scrubbers by changing the packing material or operating conditions.

The absorption of nitrogen oxides in water was investigated experimentally in a column equipped with Helix structured packing for different operating conditions (NO_x inlet concentration, specific gas, and liquid flow rate) [655]. The experimental data were compared with the absorption efficiency predicted by three models, the first obtained by the open literature and the others developed in this work. Some conclu-

sions about the relative importance of the different mass-transfer mechanisms involving the absorption process were deduced.

An industrial reactive separation process for NO_x absorption into water and nitric acid was investigated, and gas-phase and liquid-phase concentrations were measured *in situ* while operating conditions such as temperature, pressure, and absorbent flow were varied [656]. A comprehensive mass transfer/reaction model was developed and compared to the field process data used for validation. The model accurately predicted NO_x removal from the gas (i.e., typically within 3.5% of the plant data). The model successfully predicted changes in performance when key operating parameters such as temperature and pressure were varied. The addition of a bleaching solution resulted in a significant improvement in NO_x removal.

At NASA Kennedy Space Center, a vent gas scrubber/fertilizer-producing system near launch pad 39A captured dinitrogen tetroxide vapor that was vented after it was transferred from ground storage tanks into the Space Shuttle flight tanks. The scrubber used dilute hydrogen peroxide to produce nitric acid, which was then neutralized by potassium hydroxide and converted to potassium nitrate, a fertilizer that was to be used on the on-site orange groves that Kennedy Space Center leases to outside companies [645].

Spent and saturated NO_x scrubber liquor can be destroyed in an incinerator [657].

8.8.2.1 Flare Stack Installations for NO_2 Disposal

Another method for disposal of N_2O_4 vapor is to feed it into a burner torch fueled with methane or natural gas and flare it off, but the NO_x destruction is not complete because such flames in air would form some NO_x even in the absence of any N_2O_4 fed into them. Some of the TITAN-II test installations had a flare stack with natural gas into which the nitrous fumes were fed into the fuel-rich kernel of the flame [658].

A flare burner for destruction of waste oxidizer vapors was designed and developed by Martin-Marietta during the late 1960s, and several burners were installed at NASA WSTF and Vandenberg Air Force Base, as well as at Martin-Marietta's Denver division. The unit was originally designed for use at TITAN-II sites. This unit consists of a cylinder 20 cm (8 in) in diameter and 0.9 m (3 ft) in length, containing a plenum into which propane and waste N_2O_4 vapors are injected, and a burner head. The plenum was designed in such a way that the propane and N_2O_4 do not come into contact with each other until they reach the exit plane of the burner. A wind shroud protects the head from flame-out. A continuous pilot is provided at the top of the burner head to ignite the gas mixture. Approximately 4.5 kg (10 lb_m) per minute of N_2O_4 can be destroyed in the case of the 8-in configuration.

8.8.3 Spill Response and Neutralization

Hazmat teams are specifically trained on how to deal with propellant spills, either off site or on site. A computer program can assess the type of response needed to bring the situation under control, depending on the type and quantity of propellant spilled, the proximity to populated areas, and geographic conditions [659].

Accidental and unintentional spills of N_2O_4 are an acute inhalation and potentially a fire hazard and need to be neutralized immediately. If organic insulating material (polyurethane foam, polystyrene foam) becomes soaked with N_2O_4 , it constitutes a fire and explosion hazard. The foam may auto-ignite on contact with N_2O_4 . Organic foams and fibers (often wrapped around thermal conditioning lines) must not be present near N_2O_4 test installations. The choice for a method of spill neutralization is between gaseous, liquid, or solid dispersion and neutralizing agents. The main concern in case of a propellant spill is the vapor containment and mitigation.

Before even trying to apply absorbent or neutralizing chemicals to the spill, one should try to suck up the puddles of liquid with a hose and collect them in a specially designed vacuum cleaner with cold traps [660].

Covering up a propellant spill with a layer of aqueous foam will not neutralize it, but it will prevent or retard vaporization for a limited time while plans for more permanent neutralization of the propellant spill are made and equipment for remote manipulation of the spill is put in place. High-expansion foams can both quench fires and form a temporary but sufficiently durable barrier to limit the concentrations of vapors from spilled combustible and/or toxic liquids to acceptable levels.

8.8.3.1 Dispersing Gas

Accelerating the evaporation and dispersing the fumes with hot air can only be used for small spills. This does not solve the spill problem; it only relocates it.

8.8.3.2 Liquid Neutralization Agents

Water mist can absorb NO_2 fumes as a first measure of control, but a substantial amount of unabsorbed NO_2 will escape [661]. The water should be cold because NO_2 dissolves more readily in cold water than in hot water. The water droplets should be finely dispersed to maximize the interface surface area where the physical absorption takes place. A water jet like that from a fire hose is less effective [662]. Laboratory-scale investigations showed that water fog provided one of the best means for controlling toxic fumes from individual spills of NTO, hydrazine, or UDMH.

In order to determine the rate of $\text{NO}_2/\text{N}_2\text{O}_4$ absorption in a water spray, laminar water jets of different lengths were exposed to a pure $\text{NO}_2/\text{N}_2\text{O}_4$ mixture at pressures between 0.06 and 0.3 atm [663]. The amounts of HNO_2 and HNO_3 found by chemical analysis in the liquid leaving this absorption system were interpreted in terms of the absorption of N_2O_4 and its subsequent reaction. The manner in which these N_2O_4 absorption rates depend on the partial N_2O_4 pressure and the jet length strongly supported the working hypothesis that N_2O_4 is preferentially absorbed under simultane-

ous reaction with water according to a fairly rapid first-order rate formula. From these measurements, values for

$$H\sqrt{k_1D}$$

at 293 and 303 K (20 and 30 °C) were obtained where H is the solubility coefficient of N_2O_4 in water, D is the diffusivity of N_2O_4 in water, and k_1 is the reaction velocity constant.

If insufficient water is applied to a puddle of N_2O_4 , the heat of reaction may actually accelerate the rate of evaporation of N_2O_4 and worsen the situation [558]. This is also the case if a dilute caustic solution is applied to a puddle of N_2O_4 , but in insufficient quantity [658, 664]. One poorly informed source of first-response information recommended the use of a caustic solution containing sodium dichromate or potassium dichromate, oxidizers that achieve a rapid conversion of nitrite into nitrate and more rapid solution of the fumes. However, chromium(VI) pollution in wastewater is much worse than a little nitrite!

8.8.3.3 Solid Material Spill Neutralization Kits

Uniform porous nano-sized spherical $Ca(OH)_2$ powder prepared by a CaO hydrolysis-azeotropic distillation method can be used to neutralize leaking liquid N_2O_4 in an emergency [665]. The particle size of $Ca(OH)_2$ should be 200–300 nm, the pore diameter should be 8–15 nm, and the specific surface area should be $63\text{ m}^2/\text{g}$. A portable leakage disposal device can be made by putting the prepared powder into a pressure bottle such as a dry chemical fire extinguisher. Leakage can be controlled by spraying the powder over the leakage under pressure. Experimental results showed that the removal rate of NO_2 gas can be up to 90%. Through combined adsorption, absorption, infiltration, and interfacial chemical reactions, $Ca(OH)_2$ powder captures NO_2 gas and covers up leaking liquid, preventing its evaporation and diffusion.

Spilled gelled NTO or RFNA would evaporate more slowly and constitute less of a hazard than ungelled NTO or RFNA. See also [658, 664, 666–670].

8.8.4 Demilitarization of Surplus Dinitrogen Tetroxide

In the wake of SALT and Strategic Arms Reduction Treaty (START) agreements between the United States and the USSR and its follow-on states, large quantities of hypergolic missile propellants off-loaded from demilitarized missiles had to be disposed of. The U.S. Department of Defense (DoD) concluded agreements with Ukraine and the Russian Federation under which the DoD was committed to providing both former Soviet Union states with equipment and other aid for use in eliminating their strategic offensive arms in accordance with schedules negotiated in the Strategic Arms Reduction Treaty. This effort was mostly concerned with IRFNA, HDA, and UDMH, but there was also some NTO (“Amyl”) that needed to be disposed of. The U.S. EPA Risk Reduction Engineering Laboratory conducted NTO and UDMH destruction tests in a rotary kiln

incinerator with afterburner and wet scrubber [671, 672]. N_2O_4 was fed to the diesel-fuel fired rotary kiln incinerator. The N_2O_4 oxidant was added to the burner primary air supply via an N_2O_4 feed system. For all three tests, the RKS afterburner was fired with natural gas to maintain a nominal afterburner exit gas temperature of 1363 K (1090 °C [2000 °F]). NO_x levels were quite high for the N_2O_4 tests, at 9300–10000 ppm (uncorrected) at the primary chamber exit; 8400–8800 ppm, lowered again due to dilution, at the secondary chamber exit; and 590–7100 ppm at the wet scrubber exit. Approximately 30–50% of the flue gas NO_x was NO_2 , the lower fractions corresponding to the scrubber exit location.

The disposal of RFNA (“Melanj”) and HDA will be described in *Encyclopedia of Oxidizers*, chapter “Red Fuming Nitric Acid.”

Several different methods were evaluated to not only dispose of but also convert the abandoned and unwanted rocket propellants, including Amyl and Melanj, into commercially useful products such as fertilizer.

8.9 NTO Leaks and Leak Detection

In a liquid propellant system we are concerned with internal leakage through a valve seat or burst diaphragm, as well as with external leakage. External leakage is easier to detect; internal leakage sometimes is detected only when it is already too late to correct it (as in the Mars Observer scenario). The main problem with NTO leaking into ambient air is the absorption of moisture and the formation of nitric acid, which can aggravate the leak situation and corrode metals in the vicinity of the leak. Crevice corrosion of tank shells and connectors will occur in moist environments and eat its way toward the source of the NTO at the center of the component.

Indicating paints will irreversibly change color at the point where the leakage occurred [673, 674]. They can be used for detection of NTO as well as UDMH, Aerozine-50, MMH, and hydrazine.

NTO or other propellants leaking into vacuum will cool by evaporation down to the triple-point temperature, and liquid droplets will soon freeze and turn into N_2O_4 snow. This condition was simulated by spraying liquid NTO into a vacuum chamber with visual (video camera) observation [675].

8.10 Personnel Protective Equipment for Handling of Dinitrogen Tetroxide

The level of required personnel protection will vary depending on the quantity of N_2O_4 or MON being transferred.

As a minimum of protection, personnel handling N_2O_4 must wear gloves, apron, boots, and a face shield made of N_2O_4 -resistant materials. The next level of protection would include a gas mask worn instead of or under a face shield.

Gloves, aprons, and boots can be made of PVC-coated non-combustible fabrics. If N_2O_4 is in prolonged contact with such protective clothing, it may diffuse through the fabric, and the protective gear must be discarded.

A self-contained breathing apparatus with compressed air should be available at the test site to be used in more severe emergencies.

NASA and USAF use completely enclosed self-contained air protective ensemble (SCAPE) suits during fueling operations with hypergolic propellants. The 1978 suit material was butyl-coated Nomex per MILC-38149. Boots, gloves, faceplate seal, and cuffs were butyl rubber. NO_2 has a very high permeability through many polymers, and an examination of the materials used in 1978 predicted that in a 100% NO_2 atmosphere surrounding the person, NO_2 concentration inside the SCAPE would exceed threshold limit value in 4 min. As of 1978, NASA was planning to test the whole suit in a test chamber with a 26% NO_2 concentration. This type of test had not been performed before on the SCAPE suit [676].

Full-sized operational SCAPE suits and fabric from the suits were subjected to a series of tests designed to determine the amount of exposure a wearer of the suit would receive if a spill of dinitrogen tetroxide (N_2O_4) should occur nearby [677]. The results of these tests showed that a wearer of a "stock" SCAPE suit equipped with a standard liquid air pack, if exposed to a spill resulting in a 26% increase of oxidizer in the surrounding atmosphere, would experiment no detectable concentration of NO_2 inside the suit for 15 min. Thereafter, the NO_2 concentration within the suit will increase for 35 min at a rate of 0.07 ppm per minute and then at a gradually decreasing rate until an equilibrium concentration of 3.4 ppm is attained after 100 min. The effects of liquid and vapor N_2O_4 and of liquid MMH on permeation rates and tensile strength of the SCAPE suit fabric were also investigated.

During the early years of SCAPE operations, the fabric of the suits was treated with tris(2,3-dibromopropyl) phosphate as a fire retardant. When it became apparent that tris is a mutagen and suspected carcinogen, methods were sought to wash off the fire retardant from the surface of the suits and to analyze the post-wash fabric for residual tris [678]. Soap-and-water washing was the most efficient method of removing the compound from fabricated SCAPE suits and unused material. Similar protective suits were used in TITAN-II missile silos [345] and at large TITAN-II installations and engine test sites [561].

Under normal operating conditions, a SCAPE suit is pressurized to about 12 mm (0.5 in) of water pressure from the environmental control unit airflow as regulated by the suit pressure relief valves. In order to answer a "What if ...?" question about what danger the operator might be exposed to when the suit is accidentally torn, two NO_2 sensors were installed inside a suit and tested in a $2.4 \times 2.4 \times 2.4$ -m ($8 \times 8 \times 8$ -ft) environmental chamber filled with NO_2 fumes [679]. When the suit was torn, the airflow escaped through the hole, and contaminated ambient could enter the suit very quickly.

A specification for an improved ensemble for propellant handlers was developed based on experience with existing suits that were about to be retired [680].

A group of 28 glove materials, nine suit materials, and three other materials were tested for permeability to hydrazine, MMH, and dinitrogen tetroxide following exposure to these propellants for 90 min [681, 682]. Breakthrough times were determined and correlated with static permeation rates.

An improved toxic-vapor permeation test apparatus that controlled temperature, absolute pressure, differential pressure, and equivalent concentration of NO_2 in the vapor phase more reproducibly than previously used permeating test setups was used to characterize three candidate fabric materials for propellant handlers' ensemble coveralls for hypergolic propellant servicing [683, 684]. The materials evaluated were a chlorobutyl fabric made by DuPont de Nemours and used in a rocket fuel handler's clothing outfit, another chlorobutyl fabric made by DuPont de Nemours proposed for a propellant handler's ensemble, and a chlorinated polyethylene (Cloropel) made by ILC Dover already used in a Chemtursion protective ensemble.

In hypergolic propellants spill tests at NASA WSTF, it was determined that the exterior of the protective equipment may be exposed to vapor concentrations as high as 2% N_2O_4 . These numbers were then used for permeation testing of different protective clothing materials [685, 686].

The permeability of rocket propellants through skin-protective materials was measured by weighing the propellant mass permeated per minute and per square centimeter. The detection limit was $100 \text{ pg cm}^{-2} \text{ min}^{-1}$ [687].

A comprehensive summary of protective clothing for all types of corrosive chemicals, as well as the hazards of permeation of aggressive chemicals through the protective clothing during use, is provided in [688, 689]. New designs provide for better visibility and more flexibility [690].

The efficiency of Mine Safety Appliance Company's rocket propellant canisters, model GMN-SSW, to provide protection against NO_2 and UDMH was tested [691]. Canisters manufactured in 1967 were compared to canisters made in 1971. Results of the study indicated that there was no statistically significant difference between the absorbing capacities of the new and old canisters for both contaminants. One of the built-in safety features of the canisters was a small viewing window containing a color indicator that changed from orange to blue-green when the absorbing capacity was 50–75% exhausted. The concentration $\times$ time product to a color change and to penetration at 1 ppm of NO_2 at 38 L/min was tested; penetration varied between 292000 and 517000 $\text{ppm} \cdot \text{min}$, but the color would change before that point. The study concluded that indicators on the new canisters were unsatisfactory for both UDMH and NO_2 .

If a large NTO spill occurs in the vicinity of air-conditioned office buildings, there should be a filter like a large gas mask at the air intake for the air conditioning unit [692]. A sample system has been constructed to test the ability of several types of filter materials to capture the NO_2 vapors prior to their penetration into the air conditioning system. The efficiencies of standard air conditioning filters, water wash

systems, and chemically impregnated filter materials for taking toxic vapors out of the incoming air stream were evaluated.

8.11 Reduced Spill Hazard of Gelled Dinitrogen Tetroxide

Gelling of dinitrogen tetroxide will reduce the spill hazard but will substantially increase the viscosity of the oxidizer, making it more difficult to inject it into a rocket engine and achieve atomization into small droplets. The effort to make gelled N_2O_4 often goes hand-in-hand with efforts to make gelled RFNA or gelled hypergolic fuels. Both of these applications would be very similar. Because N_2O_4 reacts with most organic gelling agents, the choice of gelling agents for N_2O_4 and MON is quite limited. Usually the same gelling agents (inorganic gelling agents, typically fumed silica) that have been tested for IRFNA will work for NTO/MON as well.

Usually, once the oxidizer is successfully gelled, the fuel to be used in the system with NTO will also be gelled. Various fuels intended to be used with gelled NTO have been tested, such as gelled MMH and gelled UDMH. The gelling agent concentration in NTO should be less than 3% [693, 694].

The saturated vapor pressure of gelled (“colloided”?) dinitrogen tetroxide was found to be lower than that of liquid dinitrogen tetroxide [695]. With increasing sample temperature, the difference of the saturated vapor pressure of dinitrogen tetroxide from liquid to gel increased. The influence of two gelling agents on the saturated vapor pressure of gelled dinitrogen tetroxide system was analyzed, and a theoretical formula of estimating the saturated vapor pressure of gelled dinitrogen tetroxide was derived. The estimated error of the formula was less than 5%.

Only very few organic gelling agents have been tested for NTO because most organics would be destroyed by reaction with N_2O_4 or might even form detonable mixtures. A copolymer of vinylidene halide and perhalogenated ethylene is chemically resistant to N_2O_4 and can be used as a gelling agent [696]. Similar polymers are available under trade names such as Kel-F. A viscous gel could be obtained by suspending 5–10% of the polymer in NTO.

9 Toxic Properties of Nitrogen Dioxide and Dinitrogen Tetroxide

Toxic properties of nitrogen dioxide and dinitrogen tetroxide could be discussed in either chapter on these two oxidizers. Often a leak originates as dinitrogen tetroxide, but by the time the fumes are accidentally inhaled by the victim, the main bad actor is nitrogen dioxide. For this reason, the dinitrogen tetroxide toxicity section is included in the chapter on nitrogen dioxide.

The hazard index, which is the vapor pressure divided by the toxicity number, of nitrogen dioxide and dinitrogen tetroxide is the highest among all currently used

rocket propellants. There have been dozens of industrial and agricultural worker fatalities due to nitrogen dioxide poisoning, although only a few of them were caused by the use of N_2O_4 as a rocket propellant. Although the previous sections in this book mostly concern N_2O_4 , the inhalation toxicity studies are done almost exclusively only with the dissociation product of N_2O_4 , NO_2 vapor, at low concentrations. In most cases the leakage and spill accidents we are concerned about will involve the equilibrium mixture of dinitrogen tetroxide and nitrogen dioxide at the natural boiling point, just above room temperature. The small percentage of N_2O_4 present in the vapor has been neglected by most investigators. The contribution of N_2O_4 to the NO_2 toxicity is unknown. In most cases, either of the two nitrogen oxides reacts quickly with water in body fluids to form nitric acid and nitrous acid. There are many summary publications on the toxicity of nitrogen oxides, mostly relating to the occurrence of nitrogen oxides in smog in polluted urban and industrial atmospheres. Relatively few experiments, many of those sponsored by rocket propellant-using agencies, have used pure nitrogen dioxide for animal exposure tests and establishment of safe tolerable limits of this pollutant.

9.1 Accident History of Dinitrogen Tetroxide

As is the case with almost all hazardous chemicals that are handled in bulk, there have been accidental spills with NTO, several fatalities, and numerous serious injuries of personnel transporting or transferring NTO or servicing NTO equipment. A very impressive summary of accidents in the United States with all hypergols, including NTO, was compiled in 2009 [553, 697, 698], and it serves as the database for “lessons learned”; anyone concerned with range safety must study these case reports and try to find a common denominator. Quite often the common denominator of accidents is human error. Another common cause is design flaw in GSE. For development of a new-hire training program for propellant handlers, a report like this should be mandatory reading.

Prior to the use of NTO in rockets and in the chemical process industry, the most frequent cause of NO_x poisoning was from NO_x evolving in top-loaded silage silos on agricultural farms. This type of poisoning is typically described under the name “silo filler’s disease” [699]. A literature search with these key words produces hundreds of publications and accident case studies.

9.1.1 N_2O_4 Accident Case Studies

Four firemen with acute toxic reactions to nitrogen dioxide inhalation were treated and observed over a period of 18 months [700]. A wide spectrum of responses was noted. All had initial symptoms of acute respiratory impairment. One subsequently developed chronic pulmonary insufficiency; the other three eventually became

asymptomatic. Because initial symptoms of acute toxic conditions are often not obvious, and delayed onset of respiratory distress and superimposed bacterial infection are distinct possibilities, patients with significant exposure to NO_2 should be hospitalized and observed for at least 48 h. After discharge from the hospital, these patients should be closely observed for at least an additional 6 weeks, since the second acute phase of the illness, which may be fatal, usually occurs with some delay.

On 7 May 1972, a tank cart at the San Diego Naval Air Station, while defueling the APOLLO 16 command module after its 27 April 1972 return from its mission to the moon, exploded because of overpressurization [701]. Forty-six persons suspected of inhaling toxic fumes were hospitalized, but examination revealed no symptoms of inhalation. An accident investigation board completed a report on the accident on 30 June 1972 [702].

While the command module RCS was being emptied of all remaining propellant using GSE designed to provide an acid/base neutralization of the propellant in both the liquid and gaseous phases so that it may be disposed of safely, the scrubber tank of the decontamination unit exploded, destroying the GSE unit and damaging the building that housed the operation. Only minor injuries were received by the personnel in the area, and the command module was not damaged. Test results showed that the failure was caused by an insufficient quantity of neutralizer for the quantity of oxidizer. This insufficiency led to exothermic nitration-type reactions that produced large quantities of gas at a very high rate and overpressurized and ruptured the decontamination tank. The ratio of neutralizer to oxidizer being detanked had been too low because of the extra oxidizer retained in the CM tanks as a result of the previous Apollo 15 parachute anomaly [703]. The decontamination unit used Delchem 2303C, a combustible fluid, as a neutralizer for the oxidizer. Delchem 2303C, manufactured by Pennsalt Chemical Company, was composed of the following materials:

riethanolamine (commercial grade)	70 mass-%
thylene glycol monoethylether	10 mass-%
ater	19 mass-%
etting agent	0.5 mass-%
nti-foaming agent	0.1 mass-%

Changes were made in GSE and the detanking procedure to prevent future overpressurization events.

A similar event had happened at NASA Eastern Test Range a few years earlier: During testing on 17 October 1965, on launch complex 19 of the Eastern Test Range, approximately 9.5 L (2.5 gallons) of dinitrogen tetroxide were drained into a 208-L (55-gallon) drum containing a mixture of 9.5 L (10 quarts) of water and 0.95 L (1 quart) of triethanolamine. The drum exploded while being moved away from the launch complex by a forklift truck.

On 24 July 1975, NTO poisoning affected the three U.S. astronauts on board an APOLLO command module during its final descent and parachute deployment while returning from the Apollo-Soyuz linkup in orbit. This was due to a switch left in the wrong position, which allowed NTO and MMH fumes to vent out of the Apollo spacecraft and then back in through the cabin air intake from the outside air after the external cabin vents were opened [704]. The NO_2 concentration was of the order of $300 \mu\text{L/L}$. The crew were exposed to the toxic gas from 24000 ft. (7.3 km) on down to landing (probably for more than 20 min). The crew members suffered from burning sensations of their eyes, faces, noses, throats, and lungs. One crewmember lost consciousness during descent. About an hour after landing, the crew developed pneumonia, and their lungs had pulmonary edema. They experienced shortness of breath and were hospitalized for 2 weeks. A week later their chest X-rays appeared to return to normal. Measurements of urinary hydroxylysine glycosides indicated that considerable collagen degradation had occurred due to their inhaling nitrogen dioxide, and the crew showed clinical and roentgenographic signs of diffuse chemical pneumonitis [705]. It was likely that collagen degradation occurred in the pulmonary parenchyma.

Another serious accident event is described in detail in [553], pages 9 through 13 and [697, 706]. Three crewmen were exposed to very high concentrations of the oxides of nitrogen. One died within minutes. Severe respiratory distress syndrome developed in the other two, one of whom survived. Twenty-one other workers were exposed to minimal to moderate concentrations of the gas. Most remained asymptomatic, whereas six had shortness of breath, cough, or hemoptysis. The three with persistent symptoms received corticosteroid therapy; the complaints resolved in two. Corticosteroid therapy for four asymptomatic patients who had moderate hypoxemia 2 weeks after the accident may have reduced the severity of the second stage of nitrogen dioxide injury. A detailed description of the event is reproduced here verbatim:

Titan II Silo Large Scale N_2O_4 Spill (8/24/1978, McConnell AFB Silo 533-7) On August 24, 1978, at McConnell AFB southeast of Wichita, Kansas, the worst reported unintentional N_2O_4 spill in US history took place. Approximately 13450 gallons of liquid N_2O_4 spilled into the underground missile silo. Two members of the 381st Strategic Missile Wing were killed and 25 more were injured from N_2O_4 liquid and vapor exposure. The silo also suffered extensive damage. The Titan II first and second stages were an A-50/ N_2O_4 bipropellant propulsion system. The loading operations were completed using a holding tanker located above ground. Once the N_2O_4 loading of the rocket's first and second stages had been completed, all that remained was disconnecting the quick disconnects (QDs) from the rocket air half couplings (AHC). The technicians wearing Rocket Fuel Handler Coverall Outfits (RFHCs) were unaware that a Teflon O-ring seal had dislodged from an upstream location, moved through the filter assembly (of which there were no filter elements installed), through the QD, and wedged itself in between the poppet of the AHC and its primary sealing surface on the Titan II (proximate cause) of the spill. This prevented the isolation of the bulk propellant in the first stage oxidizer tanks once the QD was removed. The RFHCs were similar to Self-Contained Atmospheric Protection Ensemble (SCAPE) suits that are used by the Space Shuttle Program. When the technician mechanically separated the QD from the

AHC, approximately 13450 gallons of liquid N_2O_4 poured out of the AHC and into the missile silo. Very high concentrations of NO_2 vapors traveled from the silo into the connecting cableway to the blast lock area, which was located just outside of the control center where several personnel were located. All the personnel located in the blast lock area managed to escape the vapors by exiting through the access portal at ground level. The personnel in the control center would normally be isolated from the silo, however, two technicians involved in the spill opened the airlock door to try and obtain assistance for their supervisor who was in need of immediate medical attention. The two technicians and four other control center personnel then evacuated through the emergency escape hatch, once they realized the immediate danger of the situation. The nearby town of Rock, Kansas had to evacuate about 100 people as a result of the vapors that were escaping from the silo. It was later discovered that the suit of the supervisor had failed, introducing him to dangerous levels of N_2O_4 (NO_2) vapors, which was ultimately fatal to him within minutes of being exposed. Two other technicians had removed their suit hoods while in the vapor cloud. One died nine days later. The extent of the injuries of the other technician is uncertain, however, he did survive. Repairs to the damaged 533-7 silo were attempted, but later discontinued for budgetary reasons. The silo was never returned to alert status.

Three young men died of rapidly progressive pulmonary edema of delayed onset after they inhaled fumes from an accidental nitric acid explosion [707]. Electron microscopy of their lung tissue revealed altered neutrophils and necrotic endothelial cells in alveolar capillaries. Immunohistochemistry showed small and large serum proteins, including immunoglobulin M, in the edema fluid and hyaline membranes. Increased permeability is a consequence of direct microvascular injury by inhaled nitrogen dioxide.

In the worst commercial NTO spill on record, on 23 October 1995 a cloud of dinitrogen tetroxide/nitrogen dioxide escaped from a railroad tanker car in Bogalusa, Louisiana, exposing an estimated 4000 citizens to the gas. This is an excerpt from the U.S. National Transportation Safety Board report [708]:

At 3:55 p.m. on October 23, 1995, at the Gaylord Chemical Corporation plant in Bogalusa, Louisiana, yellow-brown vapors began leaking from the dome of the DOT class 105A railroad tank car UTLX 82329 that contained a mixture of nitrogen tetroxide, which is a liquefied poisonous gas and oxidizer, and water. The vapors initially formed a plume between 10 and 15 feet in diameter. Plant personnel notified emergency response agencies and used two plant fire hoses to spray water into the plume to suppress the vapors. About 4:30 p.m. Bogalusa fire personnel arrived at the plant and set up fire hoses to help-suppress the vapors.

The head on the B-end of the tank car failed about 4:45 p.m., resulting in one end of the tank car jacket being torn away and thrown about 350 feet. The tank car was then propelled 35 feet down the track and derailed at a track bumping block. A large reddish-brown vapor cloud was released from the tank car. Vapors continued to be released from the opening in the tank car for another 36 hours until the chemical reaction that had occurred within the tank was brought under control through neutralization and dilution.

Some 3000 people were evacuated from the area as a result of the vapor cloud. Of 4710 people who were treated at local hospitals, 81 people were admitted.

It appears that the tank car had contained water that entered the tank when a leaking valve had been doused with water before it was replaced a month before the accident.

The tank car that was sent to be refilled at the N_2O_4 supplier was thought to be empty, but it still contained water when it was filled because the tare weight before filling was above the number on record. The off-normal tare weight should have alerted the operators. The mixture of water and N_2O_4 corroded the tank. Following the Bogalusa accident, the most thorough study of the health effects of N_2O_4 release from a railroad tank car was undertaken; it included measuring the association between acute low-level exposure and pulmonary symptoms; reviewing the records of three emergency departments; surveying 80 emergency department patients, 552 community residents, 21 chemical plant workers, and 29 emergency workers; and conducting a case-control study [709]. Pulmonary case status was defined as having an objective pulmonary finding noted on the emergency department record, reporting that the onset of symptoms was subsequent to the release, and being within the city limits at the time of the release. Self-reported case status was defined as reporting one or more symptoms consistent with exposure to nitrogen dioxide in the week after the release and having been within the city limits at the time of the release. Chemical exposure was characterized by proximity to, direction from, and being outdoors within 1 h after the release. Duration of potential exposure was not measured. Local emergency department visits increased fivefold in the week after the release. The most common complaints recorded in a systematic sample of 528 visits in the first 30 h after the release were headache (31%), burning eyes (30%), and sore throat (24%). Objective pulmonary findings were recorded for 41 patients in the week before and 165 in the week after the release. The odds of being a pulmonary case increased by 40% for each quarter-mile increment in proximity to the release, while the odds of being a self-reported case increased by 20% for each quarter-mile increment in proximity. People who met the pulmonary case definition were 2.5 times more likely than control subjects to have been outdoors and 6.4 times more likely to report a preexisting pulmonary condition. Emergency department visits increased five-fold, but serious acute health effects were uncommon. People who met the pulmonary case definition were six times more likely to report pulmonary symptoms than those without preexisting conditions. This study was not designed to determine any potential long-term effects of exposure.

In further evaluating reactive airway dysfunction syndrome (RADS) after exposure to dinitrogen tetroxide, a different sample of 234 patients with respiratory complaints after the Bogalusa spill in October 1995 received a complete history and physical examination, a symptom questionnaire, and pulmonary function tests [710]. Patients whose previously undocumented asthma-like symptoms persisted for 3 months after exposure to N_2O_4 had methacholine challenge testing. Of the 234 patients evaluated, six met the criteria for a diagnosis of RADS. The distance of these six patients from the source of the leak, their durations of exposure, and initial symptoms were not different from those of the sample patients who did not have RADS.

Even 13 years later, the patient questionnaire database was again subjected to another statistical epidemiologic examination and led to similar conclusions [711]. Environmental exposures from sudden events may adversely impact community residents,

often resulting in a variety of health concerns. Litigation often follows, and sorting those with effects due to the exposure from those without is often complicated and difficult. The study examined the effects of two different exposure models on claimed effects to nitrogen tetroxide from the 1995 Bogalusa railroad tank car explosion. Symptoms and physical injuries were sorted into 17 different categories and analyzed by the use of exposure models. Data from 16592 individuals who completed questionnaires dealing with their claimed adverse-health effects resulting from being in the locale of the explosion were used to assess the differences in symptoms and physical conditions for each exposure model. The data illustrated the importance of exposure assessment in evaluating sometimes-bogus claims of adverse health from an environmental exposure. The data also demonstrate the difficulties in assessing litigious, publicity, and recruitment factors. See also [712–716].

In spite of the treatment with a combination of dexamethasone and anisodamine, two victims of an NTO accident died after the treatment [717]. They had suffered severe damage of respiratory and circulation function and finally died from respiratory and circulatory failure.

10 Safety Properties of Dinitrogen Tetroxide

10.1 Detonability of Dinitrogen Tetroxide

Unlike nitrous oxide or nitric oxide, liquid nitrogen dioxide and dinitrogen tetroxide do not have a positive enthalpy of formation, and they cannot be used as monopropellants without the presence of a fuel. Just looking at the thermodynamic properties of liquid N_2O_4 , one would not expect this oxidizer to be detonable. But just to be on the safe side, the detonability of liquid N_2O_4 was tested in a setup similar to that used for card gap sensitivity testing of monopropellants and liquid explosives. Using the techniques previously developed for detonability testing of nitric oxide and nitrous oxide, the detonation characteristics of dinitrogen tetroxide as a non-boiling liquid were examined [718]. In contrast to liquid nitric oxide, liquid dinitrogen tetroxide is not detonable. Liquid N_2O_4 (273 K, 0.1 MPa) confined in a steel pipe 26.6 mm in diameter with 3.38-mm wall thickness failed to detonate when shocked with a 50-g tetryl donor close-coupled to a 0.08-mm-thick polyethylene foil or a 1.27-mm-thick steel foil attenuator that sealed the bottom of the container.

However, mixtures of N_2O_4 with toluene or nitrobenzene are detonable and have been proposed as binary explosives in bombs, where the initially separated components are mixed by an air-driven propeller only after the bomb has left the bomb-bay of the bomber aircraft and before it impacts the ground.

Confined mixtures of NTO and silicone oil may explode on contact.

Dinitrogen Trioxide

Coverage of nitrogen oxides had to be spread out over seven chapters because a single chapter devoted to the topic would have been unwieldy and made it more difficult for readers to find information on a specific compound; in addition, such an approach would have made it difficult to arrange 30 chapters among 5 subvolumes in such a way that each subvolume was about the same size. Briefer chapters made our task much easier. The other six chapters in this series are titled “Nitrogen Oxides,” “Nitrous Oxide,” “Nitric Oxide,” “Nitrogen Dioxide,” “Dinitrogen Tetroxide,” and “Dinitrogen Pentoxide.”

This chapter covers dinitrogen trioxide, N_2O_3 , which exists as a pure substance only at very low temperatures. Nitrogen forms at least six covalently bound oxides, and N_2O_3 is one of them. The peculiar property of dinitrogen trioxide is its blue color. The main application of dinitrogen trioxide is as a stabilizer and anticorrosion agent in mixed oxides of nitrogen (MON).

Pure dinitrogen trioxide, which is also known as nitrous acid anhydride, nitrogen sesquioxide, nitrogen trioxide, CAS RN [10544-73-7], exists only in the solid state [1, 2]. It starts to decompose already slightly above its melting point and converts to a blue liquid consisting of a mixture of N_2O_3 and N_2O_4 . If the temperature is allowed to increase further, and the pressure buildup is allowed to vent, the mixture begins to lose nitric oxide and becomes gradually enriched with N_2O_4 . For this reason, pure dinitrogen trioxide is not suitable as a rocket propellant oxidizer, but it is used widely in mixtures with dinitrogen tetroxide. These mixtures are called **mixed oxides of nitrogen**, or MON for short. The MON designation is followed by a number that indicates the mass-% of NO in the mixture, e.g., MON-1 or MON-3. The main reason for adding N_2O_3 (or NO) to N_2O_4 is to reduce the potential of stress corrosion of stainless-steel and titanium-alloy tanks. Next to dinitrogen tetroxide, dinitrogen trioxide is the most important oxidizer among the group of nitrogen oxides.

Pure liquid dinitrogen trioxide $\text{N}_2\text{O}_3(\text{L})$ theoretically contains 65.2 mass-% NO and in the MON designation scheme could be called MON-65.2. There should be no MON with numbers higher than 65.2.

If pure dinitrogen trioxide were used as a rocket propellant, its composition would change each time the tank was vented or the propellant was transferred from a supply tank to an empty tank. On the other hand, the low freezing point of dinitrogen trioxide makes it more attractive than pure dinitrogen tetroxide, which has a relatively high freezing point. The best compromise between vapor pressure, vapor phase losses, and composition changes during transfer and a low-freezing-point oxidizer are the $\text{N}_2\text{O}_3/\text{N}_2\text{O}_4$ mixtures containing less than 30% N_2O_3 , which were discussed in detail in *Encyclopedia of Oxidizers*, in the chapter “Dinitrogen Tetroxide.”

1 Production of Dinitrogen Trioxide

Dinitrogen trioxide can be prepared by bubbling nitric oxide gas into liquid dinitrogen tetroxide until the liquid is totally saturated with NO or by slowly adding a stoichiometric amount of oxygen to pure nitric oxide and condensing the product.

Concentrated nitric acid distilled with arsenious oxide and concentrated sulfuric acid yields nitrous acid anhydride (N_2O_3) mixed with some nitrogen dioxide.

2 Physical Properties of Dinitrogen Trioxide

The physical properties other than the melting point and the solid density of pure dinitrogen trioxide (N_2O_3) are not very well known, because this compound begins to decompose as soon as the temperature exceeds its melting point. Some of the properties are known only for equilibrium mixtures, which may contain varying amounts of dinitrogen trioxide, nitric oxide, nitrogen dioxide, and dinitrogen tetroxide (Table 1). Published data of physical properties for such mixtures vary widely, depending on the purity of the sample and the methods used for measurements. An excellent summary of the physical and chemical properties of N_2O_3 is published in Reference [2]. In many instances, the undesirable premature dissociation of N_2O_3 is suppressed by applying an overpressure of NO while the physical properties are being measured.

Determination of the physical properties of N_2O_3 is complicated by the existence of two dissociation equilibria that are not independent of each other. Both temperature and pressure affect these properties.

Table 1: Physical properties of dinitrogen trioxide.

Property name	Physical state	Property data		Literature
		SI Units	Other Units	References
Molecular mass		76.0116 g/mol	13.1559 mol/kg	[3]
Melting point	solid	171.1 K	−102 °C	[4]
Boiling point	liquid	246 K	−27 °C (extrapolated)	[4]
Density at −195 °C	solid		1.782 g/cm ³	[4]
Enthalpy of formation, (ΔH) ₂₉₈	gaseous	+82.8 kJ/mol	+19.80 kcal/mol	[5]

NIST Chemistry WebBook [3] has more reliable data, but only for the gas phase

Liquid dinitrogen trioxide at low temperatures just barely above its melting point is a dark blue liquid. At 223 K (−50 °C) it is totally opaque. The blue color of dinitrogen trioxide can be briefly observed if one acidifies alkali metal nitrite salts, where it is formed as a short-lived intermediate in the decomposition of nitrous acid HNO_2 . Solid

dinitrogen trioxide is not soluble in liquid air or in liquid oxygen (LOX). When heating liquid N_2O_3 in air, one can only observe the red-brown vapors of nitrogen dioxide.

The physical properties of pure dinitrogen trioxide are not as important as the physical properties of some of its mixtures with dinitrogen tetroxide, or MON. The physical properties of $\text{N}_2\text{O}_3/\text{N}_2\text{O}_4$ mixtures will be discussed following the chapter on the physical properties of dinitrogen tetroxide.

2.1 Freezing Point and Phase Behavior of Dinitrogen Trioxide

The freezing point and vapor pressure of the $\text{NO}/\text{N}_2\text{O}_4$ system were determined to be in the range 0–16.85 mass-% NO and 288 to 233 K (15 to -40°C) [6]. These data were subsequently confirmed using data obtained by Beattie and Vosper [7].

The freezing points of mixtures of dinitrogen tetroxide and dinitrogen trioxide, as well as those of the pure components, have been accurately determined [8]. The phase diagram of the binary mixture was discussed in *Encyclopedia of Oxidizers*, in the chapter “Dinitrogen Tetroxide.” Dinitrogen trioxide behaves as a pure compound at its freezing point. The freezing point of dinitrogen trioxide was found to be at 172.4 K (-100.7°C).

2.1.1 Phase Changes at Very High Pressures

Some nitrogen oxides transition to other nitrogen oxides at very high pressures. In the case of dinitrogen trioxide, isotope exchange occurs in mixtures of liquid N_2O_3 and NO at low temperatures and high pressures [9].

2.2 Boiling Point of Dinitrogen Trioxide

The boiling point of dinitrogen trioxide cannot be determined directly because it decomposes already before it begins to boil [1]. This happens at about 276 K (3°C). Extrapolating from vapor pressure measurements of mixtures of N_2O_3 with N_2O_4 gives only a rough estimate of the boiling point of pure N_2O_3 : 246 K (-27°C).

2.3 Density of Dinitrogen Trioxide

The density of liquid dinitrogen trioxide at 275 K (2°C) is 1.447 g/cm^3 (from CRC Handbook). Dinitrogen trioxide decomposes before it reaches critical point conditions, and an equation of state for liquid dinitrogen trioxide cannot be established. Table 2 gives density data for temperatures down to almost the freezing point of the liquid.

The density of frozen N_2O_3 at 78 K is 1.782 g/cm^3 [10].

Table 2: Density of liquid dinitrogen trioxide.

Temperature		Density
K	°C	g/cm ³
265	−8	1.464
269	−4	1.455
272	−1	1.451
275	+2	1.447
268	−5	1.444
263	−10	1.453
253	−20	1.476
78	−195	1.782
158	−115	1.694

Data source: As referenced in [2] Beattie 1963

2.4 Vapor Pressure and Vapor Phase Composition of Dinitrogen Trioxide

A study was made of the vapor composition above liquid mixtures of nitrogen dioxide and nitric oxide [1, 7]. The vapor in equilibrium with a liquid containing equimolar

Figure 1: Vapor phase composition as a function of the liquid phase composition of NO/NO₂ mixtures. (Modified from [7]. Reprinted with permission from © 1961 The Royal Society of Chemistry.)

amounts of nitrogen dioxide and nitric oxide is almost exclusively nitric oxide. The composition of the vapor above liquid mixtures of nitric oxide and nitrogen dioxide is nearly independent of temperature for a particular liquid composition.

Figure 1 shows the vapor phase composition as a function of the liquid phase composition of NO/NO₂ (i.e., N₂O₃/N₂O₄) mixtures. The parameter x is the oxygen atom fraction expressed in multiples of the nitrogen atom fraction for a fictitious compound NO _{x} . The abscissa scale shows the fractional x of the NO _{x} vapor composition, and the ordinate scale shows the fractional x of the NO _{x} liquid phase composition. It can be seen that up to liquid $x = 1.4$ the vapor composition stays close to that of NO_{1.0}. The squares designate the pure compounds NO and NO₂ (i.e., N₂O₄) at either end of the curve.

2.5 Thermodynamic Properties of Dinitrogen Trioxide

The ideal gas chemical thermodynamic properties for NO, NO₂, N₂O₃, and N₂O₄ for the temperature range 50 to 5000 K were evaluated by a statistical thermodynamic method using an updated set of molecular parameters [11].

2.5.1 Heat Capacity of Dinitrogen Trioxide

The heat capacity of gaseous dinitrogen trioxide at 298 K is 65.615 J mol⁻¹ K⁻¹. The heat capacity as a function of temperature can be calculated from the following polynomial equation:

$$C_p^\circ = A + B \times \tau + C \times \tau^2 + D \times \tau^3 + \frac{E}{\tau^2}$$

where C_p is the heat capacity in J mol⁻¹ K⁻¹, τ is the temperature in kelvin divided by 1000, and A, B, C, D, and E are constants listed in Table 3 for two different temperature ranges. Note that N₂O₃ is unstable at temperatures above 298 K and the column for the higher temperature range 1100–6000 K is strictly of academic interest. It is not very practical to list thermodynamic data for a compound that is unstable at the tem-

Table 3: Thermodynamic property polynomial equation coefficients for dinitrogen trioxide gas.

Temperature Range, K	298–1100	1100–6000
A	39.09663	100.8737
B	114.8006	1.690785
C	-81.97125	-0.339747
D	21.77249	0.023407
E	-0.088738	-8.849160
F	66.46786	30.72094
G	324.5776	399.7498
H	82.84320	82.84320

Data source: [3]

perature range listed. It is much more important to have accurate thermodynamic data for liquid mixtures of dinitrogen trioxide with dinitrogen tetroxide.

2.5.2 Enthalpy of Formation of Dinitrogen Trioxide

The standard enthalpy of formation of gaseous dinitrogen trioxide at 298 K (if it existed at this temperature) would be +82.843 kJ/mol [3]. The JANAF Table listed it as +19.80 ± 0.2 kcal/mol [5]. The differential enthalpy of formation of gaseous dinitrogen trioxide as a function of temperature can be calculated from the following polynomial equation:

$$H^\circ - H^\circ_{298.15} = A\tau + \frac{B \times \tau^2}{2} + \frac{C \times \tau^3}{3} + \frac{D \times \tau^4}{4} - \frac{E}{\tau} + F - H$$

where H is the enthalpy in kJ/mol, τ is the temperature in kelvin divided by 1000, and A, B, C, D, E, and F are constants listed in Table 3 for two different temperature ranges.

2.5.3 Heat of Dissociation of Dinitrogen Trioxide

The equilibrium constant K_2 for the dissociation of N_2O_3 is

$$K_2 = \frac{[p_{NO}][p_{NO_2}]}{[p_{N_2O_3}]}$$

The equilibrium constant for the dissociation of N_2O_3 as a function of NO_2 concentration and temperature is presented graphically in Figure 2. The diameter of the circles indicates the mean deviation of the data points. The presence of NO or NO_2 retards the dissociation of N_2O_3 .

When plotting the logarithm of the equilibrium constant versus the reciprocal absolute temperature, one can derive the activation energy and heat of reaction from the slope (Figure 3). The result was 39.86 ± 0.4 kJ/mol (9.527 ± 0.096) kcal/mol for the heat of reaction [1]. The corresponding entropy change for the reaction was 139 ± 1.5 J mol⁻¹ K⁻¹ (33.25 ± 0.35 cal mol⁻¹ °C⁻¹).

2.5.4 Entropy of Dinitrogen Trioxide

The standard entropy of formation of gaseous dinitrogen trioxide at 298 K and 101 kPa is 308.54 J mol⁻¹ K⁻¹ [3]. The entropy of gaseous dinitrogen trioxide as a function of temperature can be calculated from the following polynomial equation:

$$S^\circ = A \times \ln(\tau) + B \times \tau + \frac{C \times \tau^2}{2} + \frac{D \times \tau^3}{3} - \frac{E}{2 \times \tau^2} + G$$

where S° is the enthalpy in J mol⁻¹ K⁻¹, τ is the temperature in kelvin divided by 1000, and A, B, C, D, E, and G are constants listed in Table 3 for two different temperature ranges.

Figure 2: Equilibrium constant for the dissociation of N_2O_3 as a function of NO_2 concentration and temperature. (Modified from [1]. Reprinted with permission from © 1957 The Royal Society of Chemistry)

2.6 Molecular Properties, Crystal Structure, Dipole Moment, Molecular Orbital Calculations of Dinitrogen Trioxide

Data on the molecular structure of N_2O_3 are difficult to obtain. The lack of precise gas phase structural data is largely due to the readiness with which N_2O_3 dissociates to NO and NO_2 . The peculiar blue color of N_2O_3 must be explained by transitions of electronic states in the molecule.

2.6.1 Molecular Structure of Dinitrogen Trioxide

Adducts like N_2O_3 , which are formed by association of two molecules that can exist in monomer and dimer form, are also called heterodimers. The molecular structure of

Figure 3: Arrhenius plot for the equilibrium constant for the dissociation of N_2O_3 . (Modified from [1]. Reprinted with permission from © 1957 The Royal Society of Chemistry.)

dinitrogen trioxide with interatomic distances and bond angles is shown in Figure 4. The molecule is a planar asymmetric rotor. The dashed lines marked a and b mark the two principal axes around which the asymmetric molecule can spin.

Figure 4: Molecular structure of asymmetric dinitrogen trioxide. (Redrawn and patterned after [12].)

The molecules $(\text{NO})_2$, N_2O_4 , and N_2O_3 , which form by association from other nitrogen oxides, contain weak N—N chemical bonds. They are also called homodimers $[(\text{NO})_2, \text{N}_2\text{O}_4]$ and heterodimers $[\text{N}_2\text{O}_3]$. The enthalpies of dissociation of these dimers are $\Delta H_{298} = 4.5, 57.1, \text{ and } 40.9 \text{ kJ/mol}$, respectively.

N_2O_3 has two forms, the unstable ONONO isomer and the more stable ONNO₂ form. The structure of N_2O_3 was determined from the microwave spectrum of seven isotopic species [13].

The detailed structure associated with the following planar configuration is: $d(\text{N}^2\text{N}^3) = 1.864 \text{ \AA}$; $d(\text{N}^2\text{O}^1) = 1.142 \text{ \AA}$; $d(\text{N}^3\text{O}^4) = 1.202 \text{ \AA}$; $d(\text{N}^3\text{O}^5) = 1.217 \text{ \AA}$; $\angle \text{O}^1\text{N}^2\text{N}^3 = 105.1^\circ$; $\angle \text{O}^4\text{N}^3\text{N}^2 = 112.7^\circ$; $\angle \text{O}^5\text{N}^3\text{N}^2 = 117.5^\circ$. These numbers are very similar to those shown in Figure 4.

Dinitrogen trioxide can exist both as asymmetric dinitrogen trioxide (O_2NNO) and symmetric dinitrogen trioxide (ONONO). There are other possibilities for nitrogen oxides that also have the gross formula N_2O_3 but a different structure [14]. Similar speculative structures were considered for the N_2O_3 molecule. One such theoretical isomer would be a symmetrical 2,4,5-trioxa-1,3-diazabicyclo[1.1.1]pentane, CAS RN [224950-18-9], also called the cage isomer:

or nitroso-dioxaziridine, CAS RN [132871-99-9]:

None of these compounds has ever been isolated, but they already have their own CAS Registry Numbers. Thus, keep looking for any evidence that they actually exist, perhaps only at very low temperatures.

Conformers of N_2O_3 can be isolated in a low-temperature matrix and analyzed by Fourier transform infrared (FTIR) spectroscopy [15]. The irradiation of an argon matrix containing NO and NO₂ with a pulsed laser at 355 nm caused the enhancement of

a new set of vibrational bands, which may result from the conversion of *asym*-N₂O₃ to a new conformer, *trans-cis* N₂O₃, reported at [15] for the first time. The observed vibrational frequencies and relative intensities of the conformer were in good agreement with density functional theory (DFT) calculations at the BLYP/6-31G* level. Upon annealing, a thermally induced conversion of the *trans-cis* N₂O₃ into the not quite stable intermediate *sym*-N₂O₃ takes place:

The existence of the *trans-cis* N₂O₃ was confirmed by measuring IR absorption lines of NO/NO₂/Ar or NO/O₂/Ar mixtures condensed onto a cold target at 13 K [16]. In that study, two isomers of N₂O₃, *asym*-N₂O₃ and *sym*-N₂O₃, were identified by IR absorption in an argon matrix at 13 K. Upon irradiation with a XeCl excimer laser at 308 nm, *asym*-N₂O₃ was converted to *sym*-N₂O₃ and a new form of N₂O₃, *trans-cis* N₂O₃. The latter was readily photo-converted to *sym*-N₂O₃ upon further irradiation with red light. Assignments of IR absorption lines to each conformer in its isotopic variants were based on ¹⁸O-isotopic substitution and photoconversion experiments. *Trans-cis* N₂O₃ with an *asym*. ONONO structure was identified with absorption lines at 1704.5, 1665.7, 877.8, and 243.0 cm⁻¹. Isotopic substitution indicated that this species contains two nearly isolated N=O groups. Spectral assignments were further supported by theoretical calculations with DFT methods. Previous assignments of low-energy vibrational modes of *asym*-N₂O₃ and *sym*-N₂O₃ had to be revised based on comparison with new calculations.

Structures of eight isomers of N₂O₃, including five new conformers, were investigated by computational chemistry methods [17]. The computational results showed that *asym*-N₂O₃, *sym*-N₂O₃, and *trans-cis* N₂O₃ are stable isomers, and *asym*-N₂O₃ was predicted to be the most stable. The five new isomers were much more energetic, and therefore less stable, than *asym*-N₂O₃ by an additional 314–343 kJ/mol (75–82 kcal/mol). All eight isomers were able to convert among each other through one-step or multi-step reactions. Results obtained in this work lead to the conclusion that along with the known *asym*-N₂O₃ being the nitrosating active form for N₂O₃, the *sym*-N₂O₃ and *trans-cis* N₂O₃ isomers also have relatively strong nitrosating abilities when N₂O₃ reacts with secondary aliphatic amines.

2.6.1.1 Crystal Structure of Frozen Dinitrogen Trioxide

The crystal structure of solid N₂O₃ at 113 K (–160 °C) is orthorhombic, space group *P*2₁2₁2₁, with *a* = 5.0686(4) Å, *b* = 6.4796(5) Å, and *c* = 8.6326(6) Å; *d*_c = 1.781 g/cm³ for

$Z = 4$ [18]. The structures were solved by direct methods and refined by least-squares to $R = 0.022$.

Mixtures of N_2O_3 and N_2O_4 were prepared from measured volumes of NO and O_2 for the purpose of studying phase relations in the system N_2O_3/N_2O_4 , which depend on the composition of the samples and on the temperature. Single crystals of phases A and B of N_2O_3 were grown *in situ* on a diffractometer and studied at temperatures between 166 and 103 K (−107 and −170 °C) by XRD [19]. The structural analysis of A- N_2O_3 (tetragonal, space group $I4_1/a$ at 103 K [−170 °C], $a = 16.2557(16)$ Å, $c = 8.8049(13)$ Å, $Z = 32$, $R_1 = 0.051$) was hampered by twinning and additional disorder of one of two crystallographically independent molecules. B- N_2O_3 is nicely ordered with one molecule in the asymmetrical unit (orthorhombic, space group $P2_12_12_1$, at $T = 113$ K = −160 °C, $a = 5.0686(4)$ Å, $b = 6.4796(5)$ Å, $c = 8.6326(6)$ Å, $Z = 4$, $R_1 = 0.023$). The most interesting features of the N_2O_3 molecule are its planarity and the extraordinarily long N—N bond (1.890(1) Å).

2.6.1.2 Rotational Barriers in Dinitrogen Trioxide Molecule

The rotation of two halves of the molecule around the long axis of the N_2O_3 molecule is not unhindered but similar to situations in N_2O_4 or N_2H_4 , where the rotation has barriers where the orbitals of the outer atoms overlap and repel each other. Torsional energy potentials for N_2O_4 and N_2O_3 were calculated based on optimized geometries of the respective 90°-twisted saddle points [20]. These potentials were refined by obtaining potential energies of points along the intrinsic reaction coordinate. A comparison was made between these *ab initio* potentials and an analytical form based on a two-term cosine expansion in terms of the N—N dihedral angle. The shapes of these two potential curves were in close agreement. The torsional barriers in N_2O_4 and N_2O_3 obtained from the calculations were 2333 and 1704 cm^{-1} , respectively. In the case of N_2O_3 , the torsional frequency found from the intrinsic reaction coordinate potential, 144 cm^{-1} , was considerably larger than the reported experimental values 63–76 cm^{-1} . Consistent with this discrepancy, the torsional barrier obtained from several different calculations, 1417–1718 cm^{-1} , was higher than the value of 350 cm^{-1} deduced from experimental studies. It was suggested that the assignment of the torsional mode in N_2O_3 should be reexamined. Both N_2O_4 and N_2O_3 exhibit strong hyperconjugative interactions of in-plane O lone pairs with the central N—N σ^* antibond. The torsional barriers in these molecules arise principally from a combination of 1,4 interactions and hyperconjugation.

2.6.1.3 Bond Energies and Bond Lengths of Dinitrogen Trioxide

The N_2O_3 molecule can be described as a complex formed between NO_2 and NO. It has a binding energy of about 40 kJ/mol, which is higher than that of a van der Waals adduct but much lower than that of a typical covalent bond. The N—N bond length of 1.864 Å is between that of $(NO)_2$ ($r_{N-N} = 2.236$ Å) and that of $(NO_2)_2$ ($r_{N-N} = 1.75$ Å).

In equilibrium mixtures of NO and NO₂, there is a large concentration of N₂O₄ and a smaller but significant concentration of N₂O₃, depending on the temperature.

Over the course of an all-electron STO-6G valence-bond study of the origin of the long, weak N—N bond of *asym*-N₂O₃, special attention was given to the valence-bond structures, which differ in the locations of eight electrons among five overlapping nitrogen and oxygen atomic orbitals, designated as p1, h2, and p3 for NO₂, and h4 and p5 for NO [21]. These orbitals accommodate the electrons of the N—N s-bond and oxygen lone-pair electrons prior to any delocalization of the latter electrons. The calculations were parametrized so that estimates of the atomic spin densities for NO₂ and NO were approximately reproduced when their odd electrons were assumed to occupy these overlapping atomic orbitals. The origin of the N—N bond lengthening was shown to be associated with **(1)** the orientation of the h4 atomic orbital and **(2)** some delocalization of oxygen p electrons into the nitrogen h2 and h4 atomic orbitals when the latter orbitals are initially singly occupied. Covalent-ionic resonance

can stabilize the N₂O₃ relative to the NO₂ and NO dissociation products.

2.6.1.4 Molecular Orbital Calculations of Dinitrogen Trioxide

Because it is so difficult to measure physical and thermodynamic properties of pure dinitrogen trioxide due to its incipient decomposition, computational chemistry had to step in and fill some of the data gaps.

Localized molecular orbitals were derived from the molecular orbitals calculated by a Complete Neglect of Differential Overlap (CNDO) method for N₂O₂, N₂O₃, and N₂O₄, and the theoretical Lewis structures were given [22]. The molecules have σ-type nitrogen-nitrogen bonds of high p-orbital character, but no π bonds. Oxygen lone electron pair delocalization to both nitrogen atoms is antibonding, reducing the strength of the nitrogen-nitrogen bond. These results from a semi-empirical CNDO method were in good agreement with those from previous *ab initio* studies.

The structure of symmetric N₂O₃ was investigated using *ab initio* methods and results were compared with density functional calculations of the symmetric and asymmetric forms of this molecule [23]. Bond lengths and bond angles were determined using both SCF and MP2 theory. At the highest level of theory considered, the N—O bond was determined to be 1.492 Å, the N—O bond was 1.168 Å, the ∠N—O—N angle was 103.5°, and the ∠O—N—O bond angle was found to be 109.9°. The molecule was determined to be planar at all levels of theory considered. Vibrational frequencies were computed for the symmetric structure of N₂O₃. The calculated vibrational frequencies were in better agreement with the alternate assignments than the preferred assignments reported previously. An attempt was made to determine the relative stability of the symmetric and asymmetric forms of this molecule.

Equilibrium geometries, dipole moments, harmonic vibrational frequencies, and IR intensities were calculated for a set of dinitrogen trioxide conformers by *ab initio*

calculations at the MP2 level [24]. The calculation results satisfactorily reproduced the experimental structural and vibrational spectral features of *asym*-N₂O₃ and *sym*-N₂O₃. Calculations at the same levels indicated that the *trans-cis* N₂O₃ is actually a stable conformer of N₂O₃, and previously observed matrix IR spectral features that were not properly assigned should be attributed to the *trans-cis* structure of dinitrogen trioxide. However, other results showed that the other two estimated conformers, *cis* N₂O₃ and *cis-cis* N₂O₃, must be considered to be transition states.

Ab initio calculations on three hypothetical nitrogen-oxygen clusters, N₂O₃, N₄O₆, and N₈O₁₂, with highly symmetrical geometries, *D*_{3h}, *T*_d, and *O*_h symmetry, respectively, showed that these structures have local minima, with energies very high above the products of a fragmentation reaction (N₂ and O₂) [25].

The geometrical, electronic, and thermodynamic parameters of three known isomers of N₂O₃, including the structure of the asymmetrical isomer, NONO₂, were calculated by DFT [26]. From the calculation of vibrational frequencies it followed that the structure of NONO₂ has a local potential energy minimum and corresponds to the stationary state of the N₂O₃ isomer. The molecular structure of NONO₂ is characterized by a substantial negative charge on the NO₂ fragment and positive charge on the NO fragment. The electronic structure of the NO⁺NO₂⁻ isomer can be characterized as nitrosonium nitrite, which can be oxidized to nitrite and participate in nitrosylation in accordance with the biogenic characteristics of the NO_x intermediate, assumed to be formed in biological systems during the oxidation of NO.

The cage isomer of N₂O₃ (c-N₂O₃) is an intriguing energetic oxidizer if only it could be made cheaply (from air?) and stabilized. *Ab initio* electronic structure calculations showed that c-N₂O₃ is vibrationally stable with a large heat of formation of +7.95 kJ/g [27]. Combustion reactions with c-N₂O₃ as the oxidizer would produce larger enthalpies of combustion than other commonly used oxidizers such as ammonium perchlorate (AP), Liquid **O**Xygen (LOX), or Di**N**itrogen **T**etr**O**xide (NTO). c-N₂O₃ was shown to have a unimolecular decomposition barrier of 24.4 kJ/mol at the **C**oupled **C**luster **S**ingles and **D**oubles (CCSD)(T)/CBS(Q-5) level of theory and a dimer-induced decomposition barrier of 100.8 kJ/mol. Unfortunately, although c-N₂O₃ is predicted to perform well as an oxidizer, the low barrier to unimolecular decomposition is likely to render it impractical as an energetic oxidizer.

2.7 Optical Properties of Dinitrogen Trioxide

The most peculiar property of dinitrogen trioxide is its deep blue color. The analysis of a mixture of nitric oxide, nitrogen dioxide, dinitrogen tetroxide, and dinitrogen trioxide by UV spectroscopy is simplified by the fact that nitric oxide is transparent above 2300 Å at normal pressure, while dinitrogen tetroxide is transparent above 4000 Å. Optical methods are important for the analysis of mixtures of nitrogen oxides.

2.7.1 Ultraviolet/Visible Absorption Spectra of Dinitrogen Trioxide

Early workers studying absorption spectra of liquid N_2O_3 found a band system in the 3000–4000 Å region that was initially attributed to dinitrogen trioxide. However, it was suspected that this spectrum was due to the presence of nitrous acid which would have to be expected if the reacting gases were not perfectly dry. This was supported by a study of the isotopic shift effect for the band system, where H_2O or D_2O was deliberately added to a mixture of nitric oxide and nitrogen dioxide. It was also noted that the absorption in the red or orange that leads to the blue color of liquid N_2O_3 has not been observed in the gas.

The spectrum of dinitrogen trioxide in several solvents has shown the presence of a weak absorption maximum at about 7000 Å and an intense absorption, similar to that in the gas phase, below 3500 Å. The blue color is due to a weak band in the red region, at 6620 Å in toluene, with an absorption coefficient of 4.5×10^{-4} . The visible band shifts toward the blue with increasing polarity of the solvent [28]. If one assumes that dinitrogen trioxide is fully associated in toluene at 193 K (–80 °C), it is possible to calculate extinction coefficients for quantitative analytical purposes.

The visible spectra and absorption coefficients of liquid mixtures of nitrogen dioxide and nitric oxide have been determined over a range of temperatures [29]. When corrected for changes in density, the spectra were temperature-independent. Further, the amount of dinitrogen trioxide present was nearly equal to the quantity of nitric oxide absorbed. Thus, it appears that the only major molecular species present in this system are dinitrogen trioxide and dinitrogen tetroxide. Existing data were used to relate the stability of dinitrogen trioxide at a given temperature to the partial pressure of nitric oxide in equilibrium with the liquid.

2.7.2 IR Absorption Spectra of Dinitrogen Trioxide

Dinitrogen trioxide is a planar, near prolate asymmetric top molecule with several low-frequency vibrational modes. Consequently, each of its IR bands contains a multitude of lines because many rovibrational levels are thermally populated and each can undergo transitions of significant intensity to a number of rotational states in a given upper vibrational level. The patterns are complex so that no simple pattern of lines is evident. Because of the spectral congestion caused by the small rotational constants of N_2O_3 and the presence of several overlapping hot bands, there are no reports of a completely rotationally resolved IR spectrum of N_2O_3 .

Dinitrogen tetroxide was an unwanted contaminant during the recording of IR spectra of N_2O_3 in the gaseous, liquid, and solid states. Therefore, a sample of mostly N_2O_3 in N_2O_4 was prepared and the IR spectrum measured [30]. Table 4 gives the wavenumbers of absorption bands that were only found in the $\text{N}_2\text{O}_3/\text{N}_2\text{O}_4$ mixture and that were **not** previously seen in the “pure” N_2O_4 sample.

Dinitrogen trioxide may have additional absorption bands not shown in the table above but that overlap with N_2O_4 absorption bands.

Table 4: IR spectrum of dinitrogen trioxide.

Physical state	Wavenumber, cm^{-1}	
	Solid	Gas
Temperature, K	93	293
Temperature, $^{\circ}\text{C}$	-180	20
		2164
	2090 w	2053
	1870 s	1830
	1590 s	1615
	1304 s	1309
	782 m	770

* s = strong, m = medium, w = weak.

Data source: [30]

Gaseous N_2O_3 was produced by the equilibrium reaction of NO with NO_2 . By careful selection of the temperature and pressure, the relative concentration of N_2O_3 was high and its IR spectrum was obtained without interference from other nitrogen oxide absorptions. The gas-phase IR spectrum of N_2O_3 between 300 and 2000 cm^{-1} was then recorded at $1\text{--}5\text{ cm}^{-1}$ resolution [31]. The spectrum revealed new features previously unreported including sequence bands containing torsional vibrations and provided a tentative assignment of all the N_2O_3 vibrational frequencies. An estimate of the internal rotation potential function indicates a barrier height of the order of 1 kcal/mol. Some of the frequency assignments, in particular the assignment of an absorption at 337 cm^{-1} to ν_8 in contrast to an earlier assignment of $600\text{--}700\text{ cm}^{-1}$ for this fundamental, later had to be revised in the light of Raman studies of N_2O_3 . The Raman spectrum showed a strong band at 627 cm^{-1} , which must be due to a fundamental vibration to account for its intensity.

When dinitrogen trioxide was formed in a frozen nitrogen matrix, it displayed a vibrational spectrum very similar to that of the gas-phase, asymmetrical molecule (*asym*- N_2O_3). On near-IR irradiation at 20 K, however, this structure was converted to an isomeric form with absorptions at 1689.7, 1661.0, 969.4, 704.3, 387.4, and 365.5 cm^{-1} [32]. Both ^{15}N and ^{18}O labeling showed that this isomer (*sym*- N_2O_3) had conventional, nitrite-like bonding and an extended, symmetric configuration:

The spectral region responsible for the matrix-photolytic conversion of *asym*- N_2O_3 into *sym*- N_2O_3 was $7000\text{--}9000\text{ \AA}$, a region in which *asym*- N_2O_3 absorbed (maximum, near $7200\text{ \AA}$). The *sym*- N_2O_3 could be converted quantitatively back into *asym*- N_2O_3 through irradiation in the UV region, $3700\text{--}4800\text{ \AA}$. UV absorption features at 3630, 3810, and $3980\text{ \AA}$ appeared in the spectra of matrix samples during IR-photolytic production of *sym*- N_2O_3 . These features disappeared during the UV conversion of *sym*- N_2O_3 back

into *asym*-N₂O₃. It was estimated that the symmetric nitrite-like structure of *sym*-N₂O₃ was no more than 5±10 kcal less stable than the asymmetric form. See also [33].

It is difficult to obtain pure samples of N₂O₃ for measuring its absorption spectra because even at low temperatures there is usually some NO that had formed as a result of N₂O₃ dissociating in reversal of its formation from NO₂ and NO. The fundamental and first three overtone bands associated with the ν_1 (N—O stretching) vibration of the planar, asymmetric top molecule N₂O₃ low-pressure (1–92 mm Hg) vapor were studied at 230 K using a high-resolution FTIR spectrometer and 20-m path lengths [12]. Even for the ν_1 band, where the spectrum was obtained at a resolution of 0.005 cm⁻¹, the complexity of the rotational structure defied complete analysis. However, it is possible to deduce the wavenumbers of the band origins ($\nu_1^\circ = 1829.535(2)$, $2\nu_1^\circ = 3628.03(5)$, $3\nu_1 = 5394.124(10)$, and $4\nu_1^\circ = 7128.5 \pm 1 \text{ cm}^{-1}$) and, for ν_1 , $2\nu_1$, and $3\nu_1$, the rotational constants A' , B' , and C' . Hot bands made a considerable contribution to the spectra in the region of each main band. Both the $2\nu_1$ and $3\nu_1$ vibrational levels lie well above the dissociation limit for the weak N—N bond in N₂O₃. The upper states of the overtone bands all lie above the dissociation limit for N₂O₃ → NO + NO₂. The linewidths observed for some transitions in the $2\nu_1$ and $3\nu_1$ bands indicated lifetimes of (180–300) ps and >150 ps, respectively, indicating that intramolecular energy flow from the ν_1 mode is relatively slow and that, in this respect, N₂O₃ exhibits unusual behavior. The wavenumbers for the fundamental modes in N₂O₃ are given in Table 5.

Table 5: Fundamental modes of vibration and band assignments in N₂O₃.

Fundamental mode	Wave number, cm ⁻¹
ν_1	1832
ν_2	1652
ν_3	1305
ν_4	774
ν_5	415
ν_6	241
ν_7	(205) ??
ν_8	622
ν_9	70

Data source: [31] and [12]

Figure 5 shows low-dispersion spectra of the ν_1 , ν_2 , ν_3 , and ν_4 bands of N₂O₃ at 230 K. The sharp lines in these spectra must be attributed to NO or other impurities.

At higher resolution, the ν_1 area around 1838 cm⁻¹ showed a multitude of resonances with two bands standing out due to their intensity (Figure 6). The congestion of the N₂O₃ IR bands is so great that a full analysis of the rotational structure would probably be impossible, even if greater instrumental resolution were available.

Figure 6: High-dispersion spectra of a small section of the ν_1 band of gaseous N_2O_3 at 230 K. (Reproduced from [12] with permission granted by Taylor & Francis, www.tandfonline.com.)

The IR spectrum of the ν_3 band of N_2O_3 in the dilute subatmospheric gaseous state has been measured at 1304 cm^{-1} using a slit-jet cooled tunable-diode-laser spectrometer [34]. A total of 439 IR transitions were fitted to a precision of 0.0003 cm^{-1} . Improved ground state rotational constants were calculated from ground state combination differences up to $J'' = 20$, $K''a = 10$. A number of weak perturbations were seen in the spectrum characterized by interaction matrix elements of $0.002\text{--}0.01\text{ cm}^{-1}$. The ν_3 band of N_2O_3 was scanned from 1297 to 1310 cm^{-1} with approximately 60% wavenumber coverage using two diodes. The linewidths were typically about 45 MHz, and center frequencies were estimated to be precise to about $\pm 0.0003\text{ cm}^{-1}$. The gas mixture used to study the N_2O_3 spectrum was 6.6 kPa (50 mm Hg) NO_2 and 20 kPa (150 mm Hg) NO diluted to a total pressure of 80 kPa (600 mm Hg) with Ar. A reference sample of pure N_2O was used to obtain absolute wavenumber calibration.

The ν_1 fundamental band in N_2O_3 gas was recorded in absorption at high spectral resolution with a Fourier transform interferometer, under jet-cooled experimental conditions [35]. The rotational structure, corresponding to 44 K rotational temperatures, could be analyzed, leading to a set of precise upper state parameters. The absence of b-type lines in the spectrum, expected to occur from the direction of the Q_1 normal coordinate with respect to the principal axes of inertia, can be justified by supporting *ab initio* calculations, confirming the decisive role of the polarizing NO_2 chromophore in tilting the corresponding induced dipole moment toward the direction of the a axis.

The rotational spectra of the ground vibrational state and the $\nu_9 = 1$ torsional state were reinvestigated and accurate spectroscopic constants of *asym*- N_2O_3 determined [36]. The torsional frequency, $\nu_9 = 70(15)\text{ cm}^{-1}$, was determined by relative intensity measurements. The assignment of the IR spectrum was slightly revised and an accurate harmonic force field calculated. The equilibrium structure was determined using various complementary methods – experimental, semi-experimental, and *ab initio* methods – leading to a bond length of $r_{\text{N-N}} = 1.870(2)\text{ \AA}$.

While N_2O_3 spectra had been observed in the gas phase, in solution, and as a solid at low temperatures, its spectra had not been measured adsorbed on solids at room temperature prior to 2000 [37]. The adsorbed N_2O_3 species adsorbed on dust has been postulated as a precursor to HONO in the lower atmosphere, where it plays an important role in atmospheric pollution. The IR spectra of N_2O_3 adsorbed on a porous glass surface at room temperature from the precursors NO and NO_2 were measured using transmission FTIR spectroscopy. The spectrum of the porous glass in the presence of NO and NO_2 showed broad peaks at approximately 1870 and 1600 cm^{-1} attributed to surface-adsorbed *asym*- N_2O_3 (ONNO_2). These peaks shifted by $30\text{--}40\text{ cm}^{-1}$ to lower wavenumbers when ^{15}N -labeled NO was used, consistent with absorption bands previously assigned by other researchers to solid *asym*- N_2O_3 at low temperature. See also [38].

2.7.3 Raman Spectra of Dinitrogen Trioxide

The Raman spectrum of N_2O_3 in methylene chloride solution was measured at low temperatures, and six lines in this Raman spectrum were assigned to N_2O_3 [39]. These Raman lines together with the IR spectrum obtained previously made possible the assignment of all fundamentals of the N_2O_3 molecule except the torsional mode. From the spectral data and from the available thermodynamic data, certain conclusions concerning the torsional frequency and the molecular structure were drawn.

Raman spectra of both asymmetric dinitrogen trioxide (O_2NNO) and symmetric dinitrogen trioxide (ONONO) were collected by stabilizing these species in nitric oxide matrices at 12 K [40]. Laser irradiation at wavelengths from 5682 to 7526 Å converted *asym*- N_2O_3 to *sym*- N_2O_3 , but wavelengths of 5145 or 4880 Å converted the symmetric isomer back to the asymmetric one. The Raman data, along with the IR spectra of several isotopic species (labeled ^{15}N and/or ^{18}O), for both molecules made it possible to resolve previous ambiguities in the vibrational assignments of these isomers and to carry out meaningful force constant calculations for both of them. The N—N stretching frequency at 266 cm^{-1} for *asym*- N_2O_3 and its stretching force constant of $f_{\text{N-N}} = 0.57\text{ mdyn/Å}$ are both characteristic of a very weak bond, although these values are higher than previously proposed. The N—O single bond stretching force constant for *sym*- N_2O_3 was determined to be 3.61 mdyn/Å .

2.7.4 Microwave Spectra of Dinitrogen Trioxide

The equilibrium data for the N_2O_3 dissociation reaction indicate that for typical pressures used in microwave spectroscopy ($\sim 10\text{ N/m}^2$) the amount of N_2O_3 is about 0.5% at 195 K (-78°C) and even less at higher temperatures. The microwave spectrum can be observed, however, and some structural information concerning the N—N bond length and planarity can be obtained [13]. The structure of N_2O_3 was determined from the microwave spectrum of seven isotopic species. The torsional vibrational frequency was measured as $124 \pm 25\text{ cm}^{-1}$. The quadrupole coupling constants for the nitrosyl nitrogen are $\chi_{\text{aa}} = -2.34\text{ MHz}$, $\chi_{\text{bb}} = 1.12\text{ MHz}$, and $\chi_{\text{cc}} = 1.22\text{ MHz}$. The dipole moments were determined as $|\mu_{\text{a}}| = 2.05\text{ D}$, $|\mu_{\text{b}}| = 0.54\text{ D}$, and $|\mu_{\text{t}}| = 2.12\text{ D}$ inclined at an angle of 9.1° to the N—N bond.

2.7.5 Refractive Index of Dinitrogen Trioxide

The refractive index of pure N_2O_3 could not be directly measured due to its instability. The refractive index of $\text{N}_2\text{O}_4/\text{N}_2\text{O}_3$ mixtures containing up to 47 mol-% of N_2O_3 were obtained at room temperature using the method of minimum deviation [41]. The results for N_2O_4 were in good agreement with the literature values. It was found experimentally that the molar refraction of an $\text{N}_2\text{O}_4/\text{N}_2\text{O}_3$ mixture could be expressed as the weighted sum of the molar refraction of the two components (see *Encyclopedia of Oxidizers*, in the chapter “Dinitrogen Tetroxide,” for $\text{N}_2\text{O}_4/\text{N}_2\text{O}_3$ mixtures). A plot of molar refraction against a mol fraction of N_2O_3 gave a straight line, which could be

extrapolated to $X \text{ N}_2\text{O}_3 = 1.0$ in order to estimate values of molar refraction and refractive index for pure N_2O_3 . Since N_2O_3 absorbs in the red region of the spectrum, the most reliable values were obtained using the mercury blue and blue-green lines. The extrapolated values for the refractive index of N_2O_3 were $n_{453.8}^{18} = 1.410$ and $n_{491.6}^{18} = 1.402$. Because of the experimental difficulties and the extrapolation of the results, these numbers are not very accurate.

2.8 Electrical Properties of Dinitrogen Trioxide

Liquid dinitrogen trioxide was treated as a non-aqueous solvent, similar to liquid dinitrogen tetroxide. The relative permittivity and electrolytic conductivity of N_2O_3 , N_2O_4 , and their mixtures were measured over a range of temperatures limited by the freezing point of the system on the one hand and its vapor pressure on the other [41]. The results for N_2O_3 are presented in Table 6.

Table 6: Electrical physical properties of liquid N_2O_3 .

Temperature, K	243	233	223	213	203
Temperature, °C	−30	−40	−50	−60	−70
Relative permittivity $\epsilon \text{ N}_2\text{O}_3$	26.41	26.65	28.01	29.50	31.13
Molar polarization P , $\text{cm}^3 \text{ mol}^{-1}$	46.5	46.3	46.0	45.7	45.3
Electrolytic conductivity $\lambda \times 10^8$, $\Omega^{-1} \text{ cm}^{-1}$	13.1	10.2	7.85	5.86	4.25
Ionic product $K' \times 10^{12}$	4.70	4.17	3.76	3.30	2.87
Equilibrium constant $K \times 10^{13}$	2.46	2.16	1.92	1.67	1.43

Data source: [41]

The values of $\epsilon \text{ N}_2\text{O}_3$ are typical for a polar but unassociated liquid and exceed slightly the corresponding values for NH_3 or NOCl at the same temperature. N_2O_3 might be expected to act as an ionizing non-aqueous solvent. The molar polarization P increased slightly with increasing temperature, as is the case for other polar liquids, e.g., SO_2 and NH_3 . For N_2O_3 , the molar polarization P and molar refraction R were estimated to be 45 and $13 \text{ cm}^3 \text{ mol}^{-1}$ at room temperature, respectively. To obtain these values, it was necessary to extrapolate the results for the density and relative permittivity of N_2O_3 from about 243 K (−30 °C) to room temperature. The large difference between P and R confirms that this molecule has a significant dipole moment. The dipole moment of N_2O_3 was estimated from the values of P and R using the Onsager relationship and a value of $2.7 \pm 0.3 \text{ D}$ was obtained ($1 \text{ D} = 3.336 \times 10^{-30} \text{ C m}$). This exceeds the value for gaseous N_2O_3 ($2.12 \pm 0.01 \text{ D}$), but in view of the uncertainty in the values of P and R and the approximations involved in the Onsager equation, the agreement was as good

as could be expected. Measurements of N_2O_3 in an inert solvent gave a dipole moment of $2.07 \pm 0.03 D$. Other sources reported a dipole moment of $2.572 D$.

To measure the electrical conductivity of N_2O_3 , it is essential that N_2O_4 be absent. At each temperature measurements were made with increasing partial pressures of NO above the liquid until a constant value was obtained that was characteristic of N_2O_3 . The results showed that N_2O_3 has significant electrolytic conductivity due to self-ionization. The most likely process involves the simple heterolytic dissociation of the $\text{N}-\text{N}$ bond, i.e.,

This agrees with the polarity of N_2O_3 and its chemical reactions.

2.9 Magnetic Properties of Dinitrogen Trioxide

Liquid dinitrogen trioxide is diamagnetic with a specific susceptibility of $\chi = -0.26 \times 10^{-6}$ CGS. For comparison, the specific susceptibility of water is -0.72×10^{-6} CGS.

3 Chemical Properties of Dinitrogen Trioxide

If N_2O_3 is allowed to evaporate in air, the NO that escapes first will oxidize to NO_2 , and the vapor space above the liquid will consist mostly of the red-brown NO_2 gas. For all practical purposes, N_2O_3 is an oxidizer, although it is rarely used as such in rocket applications in the pure form.

3.1 Dissociation of Dinitrogen Trioxide

The polar N_2O_3 molecule can undergo heterolytic and homolytic dissociation producing NO^+ and NO_2^- ions or NO and NO_2 radicals, respectively. Both of these reactions occur in the liquid state, but in the vapor state it is mostly the homolytic splitting that is also of interest for the atmospheric chemistry of air pollutants [42]:

The heat of dissociation of dinitrogen trioxide was already described in Section 2.5.3, which also contains several graphs describing the dissociation equilibria.

The rate at which N_2O_3 dissociates to NO_2 and NO (or, inversely, the rate of N_2O_3 formation from NO_2 and NO) can be measured by doping the sample with an isotope-labeled nitrogen oxide and monitor the establishment of an equilibrium [43]. See also [44].

The homolytic dissociation of dinitrogen trioxide in a number of organic inert solvents has been studied and relevant thermodynamic data were calculated [45]. The stability of dinitrogen trioxide varied considerably and could be correlated with the electron donor properties of the solvent.

For the dissociation of N_2O_3 at much higher temperatures, the ideal gas chemical thermodynamic properties for N_2O_3 and its dissociation products for the temperature range 50 to 5000 K were evaluated by a statistical thermodynamic method using an updated set of molecular parameters [11].

Extensive kinetic measurements were made on the system $\text{NO} + \text{NO}_2 \rightleftharpoons \text{N}_2\text{O}_3$ in the gas phase. Equilibrium mixtures of nitrogen oxides containing an excess of NO at 208 ± 5 K diluted with inert gases were perturbed by flash photolysis and the rate of relaxation back to equilibrium was monitored by observing the transmittance of a line from a CO continuous-wave laser selected to coincide with the ν_1 band of N_2O_3 [46]. Despite the weakness of the N–N bond, the kinetics appeared to be well represented by the rate theories formulated on the basis of rapid and complete randomization of internal energy as well as by looking at high-resolution spectra of the ν_1 , $2\nu_1$, $3\nu_1$, and $4\nu_1$ bands of N_2O_3 .

3.2 Photolysis of Dinitrogen Trioxide

Depending on the wavelength and energy of the incident light and depending on the physical state of N_2O_3 , light can have different effects on the molecule. Moderate illumination can bring about interconversions of different isomers of frozen *sym*- and *asym*- N_2O_3 . Intense illumination will cause photolysis and dissociation of N_2O_3 .

Classical trajectories were used to calculate vibrational predissociation rates of *asym*- N_2O_3 for initial conditions that include excitation of the ν_1 (NO stretch), the ν_2 (NO_2 asymmetric stretch), the ν_3 (NO_2 symmetric stretch), and the ν_4 (NO_2 bend) vibrational modes and combinations of these modes [47]. The results showed strong mode selectivity. This selectivity is in accord with the experimental results of Chewter, Smith, and Yarwood [12], which showed that intramolecular energy flow from the ν_1 mode is relatively slow and that N_2O_3 exhibits “non-Rice-Ramsperger-Kassel-Marcus (RRKM) behavior.”

3.3 Reactions of Dinitrogen Trioxide

Dinitrogen trioxide is a nitrosating agent. It reacts with primary and secondary amines [48]. All secondary amines formed the corresponding N-nitrosamine. Primary aromatic amines gave the diazonium nitrite, but the corresponding aliphatic compounds gave a variety of products, including alkyl ammonium nitrites, alkyl

nitrites, and alkenes. In some cases *n*-alkyl amines gave products with a branched alkyl group.

3.3.1 Hydrolysis of Dinitrogen Trioxide

Dinitrogen trioxide is the anhydride of nitrous acid HNO_2 . As such, one would expect its hydrolysis to yield a dilute aqueous solution of HNO_2 . But the reverse reaction also occurs in strongly acidic solutions of HNO_2 , where N_2O_3 can be found by spectroscopic analysis. Solutions of HNO_2 in 5-M HClO_4 exhibit a contribution to the UV absorbance that is quadratic in the $[\text{HNO}_2]$ concentration [49]. From the measured spectrum and the extinction vs. wavelength in the range 245–260 nm, the equilibrium constant of

$$K_1 = \frac{[\text{N}_2\text{O}_3]}{[\text{HNO}_2]^2}$$

was determined to be $3.03 \pm 0.23 \times 10^{-3} \text{ mol}^{-1}$. This information can then be used to calculate the Henry's law coefficient for the solubility of N_2O_3 in water, a reaction that would take place in a scrubber that is supposed to wash out NO_x in the pressurant gas of MON tanks that is vented. In practice, however, one would use an alkaline solution and not just plain water as the absorbent solution. N_2O_3 reacts with water only very slowly and is partially soluble in water without reaction. Addition of water to liquid " N_2O_3 " under pressure gives two layers, a dark blue lower layer and a lighter blue upper layer.

The energy differences between the lowest states of *cis* and *trans* conformers of HNO_2 and DNO_2 were determined by microwave intensity measurements [50]. The results were $\Delta E = 372 \pm 40 \text{ cal}$ for HNO_2 and $488 \pm 35 \text{ cal}$ for DNO_2 . The thermodynamic properties of HNO_2 were recalculated and yielded $\Delta H_0 = 540 (+600/-100) \text{ cal}$ for the reaction

The value of ΔH°_0 for the reaction was obtained from microwave intensity measurements of the species involved in the related reactions

and

The best value of $\Delta H_0 = 1050 \pm 300 \text{ cal}$ was in reasonable agreement with the value obtained from third-law calculations.

3.4 Analysis of Dinitrogen Trioxide

Because pure dinitrogen trioxide is not used as a rocket oxidizer, there is no need to analyze it in the pure state. However, the mixtures of N_2O_3 with N_2O_4 called mixed oxides of nitrogen (MON) need to be analyzed quite often, and those analysis methods are summarized in *Encyclopedia of Oxidizers*, chapter “Dinitrogen Tetroxide.” A vast amount of literature exists about the quantitative analysis of nitrogen oxides, including N_2O_3 , in the atmosphere, where they play an important role in air pollution and ozone depletion.

3.5 Decomposition and Thermal Stability of Dinitrogen Trioxide

Dinitrogen trioxide starts to dissociate reversibly as soon as it melts and by the time it reaches the gas phase, much of it is dissociated and short-lived. The presence of an excess of nitric oxide can retard the decomposition by the law of mass action.

While the N—N bond energy in N_2O_4 is about 56.4 kJ/mol, the N—N bond dissociation energy in N_2O_3 is lower, being close to 41.0 kJ/mol. The N_2O_3 vibrational frequencies necessary for such calculations are well known from the literature, they range from $\nu = 70\text{ cm}^{-1}$ for the torsional mode around the N—N bond to 1832 cm^{-1} for the stretching mode of the N—O bond.

The kinetics of N_2O_3 dissociation were investigated mostly in conjunction with similar studies for the dissociation of N_2O_4 , both being atmospheric pollutants. The kinetics of the

dissociation reaction was studied over a wide range of pressures by a laser-induced temperature jump relaxation method. Equilibrium mixtures at 225 K containing nitrogen dioxide, dinitrogen trioxide, dinitrogen tetroxide, and nitric oxide in argon were rapidly heated by a short pulse of CO_2 laser radiation [51]. The induced temperature jump, between 0.5 and 3 K, displaced the equilibrium toward NO_2 and NO formation. The rate of relaxation to the new equilibrium concentrations at higher temperature was monitored by observing spectroscopically the time dependence of the N_2O_3 absorption in the UV range. The following high- and low-pressure limiting rate constants for the $\text{NO} + \text{NO}_2$ recombination at 227 K were extrapolated from the experimental data:

$$k_{\text{recomb}\infty} = (3.5 \pm 1.0) \times 10^{12} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

and

$$k_{\text{recomb}0}/[\text{Ar}] = (1.0 \pm 0.5) \times 10^{15} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

respectively. The temperature dependence of the recombination rate constant, measured experimentally between 227 and 260 K, yielded the following expressions for the high-pressure and the low-pressure limiting rate constants, respectively:

$$k_{\text{recomb } \infty}(T) = (1.61 \pm 1.6) \times 10^9 T^{(1.4 \pm 0.2)} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

and

$$k_{\text{recomb } 0}(T)/[\text{Ar}] = (1.0 \pm 1) \times 10^{33} T^{-(7.8 \pm 0.8)} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

4 Toxicity of Dinitrogen Trioxide

The toxicity of dinitrogen trioxide vapor in air is essentially the same as that of nitrogen dioxide. The vapor toxicity of nitrogen dioxide is summarized in *Encyclopedia of Oxidizers*, in the chapter “Nitrogen Dioxide.” There is little chance that liquid dinitrogen trioxide would be ingested by other routes, but if it is, it would be very disastrous.

The cutaneous toxicity of liquid dinitrogen trioxide spilled on the skin would essentially be the same as that of liquid dinitrogen tetroxide, and precautions for the safe handling of these compounds are listed in the chapter on MON.

5 Handling of Dinitrogen Trioxide

Dinitrogen trioxide exists only in the solid state. The precautions for handling the liquid dinitrogen trioxide that forms as soon as the solid melts are the same as those widely practiced in the handling of liquid NTO or MON by experienced propellant handling personnel. Because liquid dinitrogen trioxide at temperatures a few degrees above its melting point is rarely used in the pure state, the risk of exposure is low in comparison to the risks involved in handling large amounts of NTO or MON.

Fluorine

Elemental fluorine, difluorine, F₂, CAS RN [7782-41-4], is one of the most powerful oxidizers.

The potential of achieving the utmost in specific impulse with chemical rocket propellants by using fluorine instead of oxygen as an oxidizer has kept many propellant chemists busy working over the years and decades. However, in the end, it was more the concern about toxicity and environmental pollution than the desire for an extremely high specific impulse that determined the types of rocket propellants that are being used today. Nevertheless, for special applications where specific impulse is at a premium, fluorine-containing rocket propellants may still fly one day in the distant future. Many non-rocket applications, such as chemical lasers and fluorine-containing pharmaceutical drugs and agrochemicals, have benefited from the fundamental work that was done for fluorine-containing rocket propellants, just as rocket applications of fluorine in the 1960s benefited from the previous use of fluorine for uranium isotope separation during the Manhattan Project at the end of WW-II. Work on chemical lasers continued even after work on fluorine rocket propellants was abandoned. Fluorine chemistry has other, often underappreciated benefits. Examples for the use of fluorine in biologically active materials are the pharmaceutical drugs LIPITOR (for high cholesterol), ADVAIR DISKUS (for asthma), and PREVACID (for gastric reflux), three of the top ten pharmaceuticals sold in 2007, containing one or more fluorine atoms. And for more than 40 years, 5-fluorouracil has been one of the leading drugs used in topical cancer chemotherapy, where it operates by altering the synthesis of deoxyribonucleic acid (DNA) in cancer cells leading to apoptosis, inhibiting growth. The antidepressant Prozac contains a -CF₃ group. Fluorine chemistry, following the pioneering footsteps of rocket propellant chemists, has developed selective fluorinating agents that allow the synthesis of such pharmaceuticals. However, the presence of fluoroalkyl groups in water-repellent plasticizers, fire-proof fabrics, and cosmetic lotions has caused concern about potential toxic effects when the chemicals accumulate in fatty tissue in the body of humans.

It is partially with the ongoing laser applications and other future non-rocket applications of fluorine and fluorine compounds in mind that this chapter on fluorine in the book at hand has been updated and it continues to be an essential part of any book on rocket propellants (or on the history of rocket propellants). Otherwise it would only be a history book. Industrial fluorine history spans about a hundred years and admittedly has had negative environmental effects such as hydrofluoric acid pollution caused by fumes from aluminum smelters and ozone depletion due to chlorofluorocarbon solvent and refrigerant emissions.

Besides the physical properties of fluorine that are of interest for those readers evaluating fluorine as a rocket propellant, this chapter contains information on materials compatibility and handling precautions for fluorine. This information material was updated and included here again in the hope that it will be of some use to engineers looking at other future non-rocket applications of fluorine. The problems arising from handling liquid fluorine and the neutralization of exhaust gases make the use of fluorine as a rocket or laser propellant an extremely difficult task. Have rocket propellant chemists of the 1960s been overly optimistic and have they ignored the critics that derided them as falling victim to their own overly optimistic imagination, chasing an illusion? The perspective from the early twenty-first century is quite different from the prevailing optimism that characterized the rocket propellant scene in the 1950s and 1960s when the author first started working on rocket propellants, including several fluorine oxidizer compounds. Since 2016, hardly any liquid fluorine is transported over public highways any longer. For many years, until after World War II (WW-II), fluorine (gaseous or liquid) was not available commercially. Then the industry geared up and offered it in various forms, including gaseous and liquefied. However, today most elemental fluorine is produced only for captive use and converted soon after to other more inert products at the same chemical plant location. Some of the fluorides prepared in this way can also be used as rocket propellants, laser propellants, or torpedo propellants. This includes non-metallic fluorides such as ClF_3 , ClF_5 , OF_2 , NF_3 , and SF_6 (see *Encyclopedia of Oxidizers*, Chapters on Halogen Fluorides, Oxygen Fluorides and Nitrogen Fluorides). When looking for additional information on fluorine oxidizers and their potential use as rocket propellants, the reader may also want to consult the literature references collected in the following Table 1. This table also contains several bibliographies on fluorine and fluorine compounds.

During the second half of the twentieth century, acute interest in the use of fluorine and fluorine compounds as rocket propellants developed not only in the US, but also in many other countries, including Russia [19], France [20], Germany [21], and the UK [22]. In spite of this multi-national effort, no actual flight uses can be reported.

The specific impulse of liquid rocket propellants is determined by the choice of oxidizers and fuels. There are many oxidizers that give a better specific impulse than the mainstay oxidizer, liquid oxygen. Of all these high-energy oxidizers, only fluorine and ozone are manufactured in industrial quantities.

It is now only of historical interest to backtrack the different opinions on the pros and cons of using liquid fluorine or liquid ozone as a rocket propellant, because we have progressed from the beginning of the space age to a mature rocket propulsion industry [23]. In the beginning, there was a short period when fluorine and ozone were competing and both were given the same chance of becoming the high-energy oxidizer of the future. Time and experience has shown that neither one seems to be worth the extra expense or increased risk.

1 Production of Fluorine

The main driver for starting and increasing the production of elemental fluorine was the use of uranium hexafluoride for isotope separation in diffusion plants, starting with the secret Project Manhattan during WW-II, continuing through the years of the Cold War, and transitioning into commercial nuclear power plants and their supply chain. The use of fluorine during the several decades while it was actively evaluated as an oxidizer in rocket propellants has benefited from this existing infrastructure in the nuclear industry.

1.1 Fluorine Resources

Because of its enormous reactivity with anything it comes in contact with, fluorine does not occur naturally in the elemental form but only in the form of fluoride compounds. Fluoride minerals that serve as a source of fluoride and fluorine are listed in Table 2.

Table 2: Fluoride minerals as sources of fluorine.

Compound name	Chemical formula	Fluoride content, mass-%	Alternative names
Fluorite	CaF_2	48.7	Fluorspar
Cryolite	$\text{Na}_3[\text{AlF}_6]$	54.3	
Apatite	$\text{Ca}_5(\text{PO}_4)_3\text{F}$	3.8	Fluorapatite

In apatite, the fluoride can be partially substituted by hydroxyl, chloride or carbonate. The hydroxyl group in hydroxylapatite, the main constituent of tooth enamel and bones, is readily exchanged for fluoride because this is one of the first known natural ion exchange column packing materials.

Looking at the elemental abundance of fluorine (fluoride) in the Earth's crust, it is surprising to learn that 0.06 mass-% of the crust consists of fluorine and that fluorine is actually more abundant than chlorine. Among the elements, fluorine ranks 24th in universal abundance and 13th in terrestrial abundance.

Most of the fluoride minerals used in the US are imported. There have been repeated (but now outdated) reports [5], lamenting the limited availability of fluoride minerals and predicting exhaustion of fluoride resources within a century. In 2014, the leading suppliers of fluorspar to the US were Mexico (77%), South Africa (9%), Mongolia (5%), and Vietnam (4%). Under these prospects it would have been unwise to build a rocket propulsion industry that will be knowingly dependent on a limited resource. However, the amount of fluorine used for rocket propulsion would have been only a small fraction of the total fluorine compound consumption. The main competing uses for fluorine are flux and molten electrolyte bath materials for aluminum electrowinning, fluorinated organic compounds (refrigerants, fire extinguishing agents, fluoropolymers, fluoro lubricants, fluoro surfactants), plate glass, and uranium isotope separation [3]. With the identification of halocarbons (predominantly fluorochlorocarbons) as causing ozone depletion and increased ultraviolet (UV) transmission of the high atmosphere, a ban on the use and release of halocarbons as pressurants ("propellants") for cosmetic aerosols and spray paint cans has reduced the amount of halocarbons produced for that application. The production of re-formulated refrigerants (R-134a replacing R-12 and R-22) still uses some fluorine, but they have a lower ozone depletion potential. The silicon chip-integrated circuit-producing industry needs extremely high purity (electronic grade) fluorine gas (diluted with inert gases) or nitrogen fluoride as an etchant in ion guns and for cleaning the vapor deposition chambers. Hydrofluoric acid is used for etching the glass of light bulbs and making window glass opaque (less transparent). Fluoride in the form of dihydrogen hexafluorosilicate (hexafluorosilicic acid) is added to drinking water in some communities where there is an inadequate natural fluoride mineral concentration to prevent tooth decay.

We are summarizing the supply situation for fluoride minerals here mostly in order to show that the limited availability of fluoride minerals would not be an impediment to the future use of fluorine or halogen fluorides as rocket propellants for specific upper stage (i.e., kick stage) space propulsion applications where the high specific impulse becomes mission-enabling and/or results in a substantial reduction of the overall vehicle launch mass.

In 2013, 134000 tons of fluorite equivalent was recovered in the US from all sources, but a multiple of that, 625000 tons had to be imported. The US dependence on imports is near 100% [24].

Additional information on the availability and production statistics of fluorine raw materials is contained in [25–28]. If a shortage of fluorite should develop, one would need to depend to a larger extent on fluoride recovered during the processing of apatite ores in the process of making phosphate fertilizers and phosphoric acid. Many phosphate minerals contain up to 3% fluoride, which is often an unwanted contaminant and cannot be safely vented to the atmosphere when the phosphate is processed with sulfuric acid into fertilizer. Downwind environmental contamination due to traces of fluoride in stack gases from fertilizer factories has caused severe problems to plant and animal life [29].

1.2 Production Methods for Fluorine

We are listing the methods of fluorine production here because elemental fluorine is (was) not industrially available in many countries and some rocket propellant development laboratories chose to make their own elemental fluorine on site. For the first hundred years of the known existence of fluorine as a free element, electrolysis of fluoride melts was the main method of fluorine production. Whereas the other halogens can be liberated from their salts by strong oxidizers, there is no oxidizer stronger than fluorine that could be used to liberate the free element from its salts. Fluorine is the element with the highest electronegativity. Only on the occasion of commemorating the centennial of the discovery of elemental fluorine was a new non-electrolytic method for the preparation of fluorine by chemical means announced by [30–32]:

During World War II, Germany had developed a substantial capability in fluorine production. A historical summary of the development of the elemental fluorine process in Germany during the war described the suitability of the various metals as anode materials and it was concluded that nickel was the most satisfactory metal up to 373 K (100 °C) [33, 34]. Different types of graphite anodes and electrolytes were tested. It was concluded that graphite was a suitable anode material at temperatures around

523 K (250 °C) and that specially prepared carbon anodes could be used between 338 and 363 K (65 and 90 °C). Operating details were given for two German cells, the high-temperature (518 K = 245 °C) Falkenhagen cell and the low-temperature (348 K = 75 °C) Leverkusen cell.

Historically, both the US and Germany developed fluorine production technology during WW-II as part of the war effort [35]. Whereas in the US, all of this effort was aimed at the production of UF_6 for isotope separation, in Germany much of the fluorine produced was converted to chlorine trifluoride, which was easier to store and which was intended as a hypergolic source of ignition for flame throwers.

When the interest in fluorine as a rocket propellant developed in the 1950s, rocket applications benefited substantially from the availability of fluorine for uranium isotope separation. The US had developed a substantial elemental fluorine production capacity as part of the Manhattan Project (development of the atomic bomb) during WW-II for making UF_6 and separating natural uranium isotopes ^{235}U and ^{238}U by diffusion of the UF_6 vapors. Fluorine is monoisotopic, so any mass differences between UF_6 molecules are due to the presence of ^{235}U or ^{238}U , enabling uranium enrichment via gaseous diffusion or gas centrifuge.

The raw material for electrochemical production of elemental fluorine is anhydrous hydrofluoric acid, which is available industrially in large quantities because it is used for many other applications. The electrolyte must not contain any water because otherwise the product would be oxygen difluoride instead of elemental fluorine. The electrolyte is a solution of potassium fluoride or potassium hydrogen difluoride in anhydrous hydrofluoric acid. The electrolyte melts at 303 to 513 K (30 to 240 °C), depending on the KHF_2 content. Three electrolysis processes have been used:

1. electrolysis of a melt consisting of $\text{KF} \cdot 2.5\text{-HF}$ on platinum or nickel anodes at 303 to 343 K (30 to 70 °C);
2. electrolysis of a melt consisting of $\text{KF} \cdot 2\text{-HF}$ on hard carbon (graphite) anodes at 353 to 393 K (80 to 120 °C);
3. electrolysis of melted KHF_2 on graphite anodes at about 523 K (~250 °C).

There are at least 40 different designs for fluorine electrolysis cells described in the scientific and patent literature. There are small cells for laboratory use with a capacity of 140 g/h, whereas large industrial units can produce more than 10 kg/h. Typically, several of these cells are combined in units that share heat sources, electrolyte maintenance, and product purification, but are wired individually. One of the early cell designs drew a current of 600 A [36].

Medium-temperature fluorine cells operated at 373 to 378 K (100 to 105 °C) using a fused-salt bath of $\text{KF} \cdot 2\text{HF}$ (melting point 344.2 K = 71.7 °C) [37, 38]. The fluorine was liberated at a carbon anode and hydrogen was liberated at a steel cathode. The cell body consisted of a welded Monel tank with a steel jacket through which water flowed for cooling and heating. In order to obtain fluorine free of oxygen and oxygen di-

fluoride contamination, the electrolyte has to be analyzed for water content prior to use [39].

A 36-cell fluorine plant was designed and operated by the Carbide and Carbon Chemicals Co. under contract to the US Atomic Energy Commission at Oak Ridge, TN, in the 1950s [40]. The plant was capable of producing, continuously, 1800 kg (4000 lb) of fluorine a day using cells that can be operated at a maximum output of 61 kg (134 lb) of fluorine per day.

Allied Chemical and other companies began to offer fluorine gas in compressed gas cylinders in 1946. Figure 1 shows a view of one of Allied Chemicals' production units in Metropolis, IL, used in the early 1960s.

Figure 1: Fluorine electrolysis production units. (Photo: Courtesy of Allied Chemical.)

Technical details on fluorine production can be found in some of the references listed in Table 3.

Improvements in the fluorine production process may be obtained by forming a ternary conducting layer $\text{CF}_x \bullet \text{M}_y$ at the surface of carbon anodes (where M is a metal: Li, Mg, Al). Electron transfer at the interface is thus enhanced and the wettability of the electrode by the $\text{KF} \bullet 2\text{HF}$ melt is improved. It was shown that polishing the carbon electrodes with alumina or magnesia actually dopes the carbon by mechanically imbedding the latter compounds [55]. Scanning electron microscopy experiments showed that particles of aluminum oxide or magnesium oxide were inserted during the polishing process and they formed the corresponding fluorides during electrolysis in the $\text{KF} \bullet 2\text{HF}$ melt. A ternary conducting compound is formed on the surface, as in the case

of electrodes doped by additions of LiF or AlF_3 into the melt. The electrochemical behavior of the polished electrodes was then studied by cyclic voltammetry experiments and impedance measurements.

The effect of the addition of LiF or AlF_3 to $\text{KF} \cdot 2\text{HF}$ melts on the behavior of the anodic carbon material during the preparation of elemental fluorine was studied using cyclic voltammetry [56]. These additions were intended to reduce the passivation of the anode. This effect was attributed to the formation of a conducting ternary compound at the interface between electrode and electrolyte. This compound is thought to enhance electron transfer at the interface and to improve the wettability of the electrode by the melt.

Fluorine is usually produced by electrolysis of molten $\text{KF} \cdot 2\text{HF}$ in medium-temperature cells at 353 to 393 K (80 to 120 °C). Non-graphitized carbon is the material that can usually be used for the anodes. However, a high anodic overvoltage is observed (~3 V in industrial cells), which results in the low energy efficiency of the process. This is caused by the formation of a passivating film of graphite fluoride at the surface of the electrodes [57]. During the direct current electrolysis of $\text{KF} \cdot n\text{HF}$ melts, a passivating film of graphite fluoride (CF_x) is formed on the carbon electrodes, leading to high anodic overvoltage. Pulsed electrolysis enables fluorine production with significant improvements [58]. Rectangular or sinusoidal wave forms have been studied.

1.3 Purification of Fluorine Gas

Fluorine produced by electrolysis of KHF_2 contains contaminants such as hydrogen fluoride (HF) carried over from the electrolyte, CF_4 , from reaction with the carbon or graphite anodes, or O_2 , O_3 , CO, and OF_2 , depending on the purity and the anhydrous operating conditions of the electrolyte in the bath. Except for O_2 , these contaminants can be condensed in cold traps. Some, but not all O_2 can be condensed in a cold trap kept at 93 K (-180°C). Oxygen is adsorbed by charcoal more than fluorine at 93 K (-180°C), and this phenomenon can be utilized for the purification of fluorine. Fluorine with a purity of 99.4% was obtained by this procedure [59]. One must remember that oxygen or fluorine condensed on charcoal constitutes an **explosive** mixture.

Hydrogen fluoride can be absorbed in towers filled with potassium fluoride (KF) or sodium fluoride (NaF) powder or granules. The absorption of HF into NaF forming the double salt NaHF_2 is so complete that this method has been used for the analysis of HF/ F_2 mixtures [60].

The exhausted absorbents in the HF absorption towers can be regenerated by heating them to 548–573 K ($275\text{--}300^\circ\text{C}$) in a stream of nitrogen gas. The regenerated NaF thus formed is very porous, has a high surface area, and is a very active absorbent for HF. A recommended method for the purification of gaseous fluorine is a combination of cold traps and absorption [61, 62]. The gas is first passed through a cold trap at 203 K (-70°C) and then through an absorption tower filled with NaF. If only one cold trap is used and it is cooled to below 190 K (-83°C), a problem may arise from solid HF clogging the trap. This method can be used in a continuous mode if two parallel trains of cold traps and absorption towers are available, one is on active duty while the other one is being regenerated and cleaned.

If large quantities of fluorine need to be purified, this can be done by fractionated cryogenic distillation using a 1.5-m-long distillation column with a vacuum jacket and filled with 1.5-mm nickel Helipak column packings [63]. The contaminants accumulated in the pot were analyzed by infrared (IR) and mass spectroscopy and shown to contain N_2 , O_2 , CO_2 , NF_3 , HF, CF_4 , C_2F_6 , C_3F_8 , OF_2 , and Ar. OF_2 can be removed and decomposed by passing it over copper shavings at 523 K (250°C).

Commercial fluorine gas may contain 1–2% impurities, primarily O_2 , N_2 , and HF with trace amounts of Ar, CO_2 , CF_4 , C_2F_6 , C_3F_8 , COF_2 , OF_2 , SiF_4 , SF_6 , O_2F_2 , and others. For most preparative purposes the O_2 content of fluorine does not interfere with the desired reactions and the purification of F_2 can be limited to the removal of HF by a NaF scrubber. There are applications where oxygen-free fluorine is needed. A typical example is the HF–deuterium fluoride (DF) chemical laser. It is known that molecular oxygen acts as an inhibitor for the chain-branching fluorine atom-generating reaction of H_2 and F_2 . In addition, the presence of O_2 causes the formation of water, which is a very strong deactivator for vibrationally excited HF or DF. In order to obtain meaningful baseline data, oxygen-free fluorine is required.

It was found that the well-known reaction

is ideally suited for the removal of oxygen impurities from fluorine [64]. Either heating or UV illumination can be used for activation of the reaction. Of these two activation energy sources, thermal activation is preferred for scalability and simplicity. In a typical example, crude F_2 (17 g = 500 mMol) and SbF_5 (2.1 g = 100 mMol) in a 1.2-L Monel reactor were heated for 2 h to 460 K. The vessel was cooled to 90 K and the F_2 was distilled into a trap kept at 77 K. The excess of unreacted SbF_5 was removed from the Monel vessel by pumping at room temperature. The vessel was opened in a dry box and contained 1.1 g of a white solid, which was identified by its vibrational spectra as $[\text{O}_2]^+ [\text{SbF}_6]^-$.

The low-temperature UV photolysis for the removal of O_2 from F_2 involves the irradiation of liquid fluorine in a quartz apparatus to convert O_2 to the less volatile O_2F_2 , followed by a distillation at 90 K [65].

The most troublesome contaminants in liquid fluorine are those that are insoluble and are carried along in particulate form, clogging filters and injection orifices. Filtration of liquefied fluorine would remove these contaminants. The fluorine could further be purified by distillation.

Filtration of the liquid was accomplished by condensing the gas in a Monel cell and forcing it through a Hoke 5–12-micron filter [66]. The filtered fluorine was analyzed by taking a sample in an IR cell or by distilling the fluorine and collecting the contaminants if any were present. In most instances, the fluorine was passed through an NaF bed to absorb troublesome HF before filtration.

If the material $\text{KF} \cdot \text{HF}$ used in the electrolysis for production of fluorine contains 0.17% Cl, the resulting fluorine may be contaminated by chlorine. The chlorine contamination occurred only at the beginning of electrolysis and ceased as the electrolysis proceeded [67].

The electrolysis of wet HF or wet $\text{KF} \cdot \text{HF}$ may also produce some ozone as a contaminant in the gas. The ozone concentration in fluorine or oxygen difluoride can be measured by gas chromatography [68].

1.4 Production Capacity for Elemental Fluorine

Most of the fluorine produced in the US during and shortly after WW-II was used for isotope separation and the capacity of these production units was classified information at that time.

From 1947 to 1960, approximately 340000 tons of liquid fluorine were produced in the USA. In many cases the liquid fluorine was not used as such, but liquefying and transporting it in cryogenic tanks from the production plants to the various customers was the most economical method, similar to the widely accepted practice of

transporting liquid oxygen to end users where it is evaporated back to gaseous oxygen. The capacity of one of the plants used by Allied Chemicals in the early 1960s was estimated at 1000 tons/year. Another source estimated the capacity as 1500 tons/year. Yet other writers estimated the capacity at 2400 tons/year [52]. For historical information on the production of fluorine the reader can consult [69–73]. For the European point of view, see [22], which explains the main ways in which British fluorine production installations differed from American ones.

2 Physical Properties of Fluorine

The physical properties of fluorine in its various states (gas, liquid, solid) are summarized in the following tables. The most comprehensive summaries of the physical properties of fluorine were compiled by researchers at the US National Bureau of Standards in Boulder, CO [74].

Fluorine has 18 isotopes, but only one of those is stable and occurs naturally. Seventeen radioisotopes with mass numbers from 14 to 31 have been synthesized, of which ^{18}F is the most stable, with a half-life of 109.7 min, and is used in medical diagnostic tools. The molecular mass of difluorine with natural isotope distribution (IUPAC 1962) is 37.9968 g/mol. See also [75].

2.1 Freezing Point of Liquid Fluorine

Liquid fluorine freezes at 53.54 K ($-219.62^\circ\text{C} = -363^\circ\text{F}$) at atmospheric pressure.

Fluorine has two solid forms, α - and β -fluorine. The latter crystallizes at 53 K ($-220^\circ\text{C} = -364^\circ\text{F}$) and is transparent and soft, with the same disordered cubic structure of freshly crystallized solid oxygen, unlike the orthorhombic systems of other solid halogens. Further cooling to 45 K ($-228^\circ\text{C} = -378^\circ\text{F}$) induces a phase transition into opaque and hard α -fluorine, which has a monoclinic structure with dense, angled layers of molecules. The transition from β - to α -fluorine is more exothermic than the condensation of fluorine, and can be violent.

2.2 Boiling Point of Liquid Fluorine

The boiling point of liquid fluorine is below that of liquid nitrogen, such that fluorine can conveniently be kept as a liquid in a surrounding bath of liquid nitrogen. The physical properties summarized in Table 4 are those fixed points that are temperature independent and a few where data were available only for one fixed temperature.

Table 4: Fundamental physical properties of fluorine.

Property	SI Units	Common Units	US Units	References
Atomic mass (F) (IUPAC 1962)	18.9984 g/g-atom			[76]
Molecular mass (F ₂) (IUPAC 1962)	37.9968 g/mol	26.3180 mol/kg		[76]
Solid fluorine phase change temperature	45.55 K	−227.61 °C	−377 °F	[77]
Melting point	53.54 K	−219.62 °C	−363 °F	[77]
Boiling point	85.02 ± 0.02 K	−188.14 °C	−307 °F	[77]
	85.21 K	−187.94 °C	−306 °F	
	84.93 K	−188.22 °C	−307 °F	[78]

2.3 Density and Partial Molar Volumina of Gaseous and Liquid Fluorine

The liquid–gas phase diagram of fluorine is given in Figure 2.

2.3.1 Density of Gaseous Fluorine

The most accurate gaseous density data for gaseous fluorine were derived from a set of pressure, volume, temperature (PVT) measurements performed at the US National Bureau of Standards (NBS) [81]. A separate NBS report [82] contains PVT measurements, virial coefficients, and a Joule–Thomson inversion curve of fluorine. The equations were derived such that the densities are represented accurately even in the proximity of the critical point. The vapor density can be fitted to the data using the following equation:

$$\ln(\rho/\rho_c) = C_1[Z/(Z-1)] + C_2Z^{0.35} + \sum_{i=3}^7 C_i Z^{i-2}$$

where $Z = 1 - T/T_c$ and the following constants apply for C_1 through C_7 :

C_1 4.85547085

C_2 −1.96015519

Figure 2: Liquid–gas phase diagram of fluorine. (Reproduced and modified from [79].)

$$C_3 \quad -1.88066900\text{E}-01$$

$$C_4 \quad 6.21165939$$

$$C_5 \quad -2.29600897\text{E}+01$$

$$C_6 \quad 4.69524623\text{E}+01$$

$$C_7 \quad -4.30650270\text{E}+01$$

and the following critical point properties were used to connect the data: $T_c = 144.31 \text{ K}$, $\rho_c = 15.10 \text{ mol/L} = 0.574 \text{ g/cm}^3$. A similar equation is given further down for liquid fluorine.

2.3.2 Density of Liquid Fluorine

For a long time dating from the discovery of fluorine by Moissan in 1886 until the 1940s, the density of liquid fluorine was reported to be much too low, owing to the lack of purity of the fluorine samples used. It was not until the 1950s that several investigators measured the density using high-purity fluorine and pointed out the error [83]. They reported a single data point of $1.54 \pm 0.02 \text{ g/cm}^3$ at 77 K (-196°C), substantially higher than any fluorine densities published up to that time. Additional data are presented in Table 5.

Table 5: Density of liquid fluorine.

Temperature			Density	
K	$^\circ\text{C}$	$^\circ\text{F}$	g/cm^3	lb/ft^3
65.78	-207.4	-341.3	1.638	102.26
71.76	-201.4	-330.5	1.594	99.51
74.93	-198.2	-324.8	1.578	98.51
78.59	-194.6	-318.2	1.550	96.77
78.62	-194.5	-318.2	1.553	96.95
81.72	-191.4	-312.6	1.532	95.64
84.34	-188.8	-307.9	1.514	94.52
85.05	-188.1	-306.6	1.505	93.96
85.67	-187.5	-305.5	1.505	93.96
86.91	-186.2	-303.2	1.496	93.39
88.26	-184.9	-300.8	1.481	92.46
90.08	-183.1	-297.5	1.472	91.90
91.55	-181.6	-294.9	1.458	91.02
94.73	-178.4	-289.2	1.434	89.52
97.56	-175.6	-284.1	1.412	88.15
100.21	-172.9	-279.3	1.391	86.84
102.75	-170.4	-274.7	1.370	85.53

Data source: [84, 85].

The data in Table 5 have been curve-fitted and can be represented by a polynomial equation that represents the data between 65 and 102K with much better accuracy than the linear equation proposed by White, Hu, and Johnston:

$$\rho = 1.907 - 2.201 \times 10^{-3}T - 2.948 \times 10^{-5}T^2$$

where ρ is the density in g/cm^3 and T is the temperature in kelvin. The uncertainty in the density was estimated to be $\pm 0.1\%$.

The liquid fluorine density data from the Jet Propulsion Lab (JPL) [86, 87] are tabulated in Table 6 and shown graphically in Figure 3 in comparison with data from other sources.

Additional liquid fluorine density data are tabulated in Table 7 and shown graphically in Figure 3 in comparison with data from other sources [88].

Table 6: Density of liquid fluorine.

Temperature, K	Density, g/cm ³
65.4	1.639 ± 0.002
67.1	1.630 ± 0.002

Table 7: Density of liquid fluorine.

Temperature, K	Density, g/cm ³
66.03	1.6331
67.98	1.6218
70.00	1.6081
72.55	1.5920
75.01	1.5761
77.22	1.5622

Data source: [88]

The density as a function of temperature between 66 and 77 K can be expressed by the following linear function [88]:

$$\rho = 1.5127 + 0.00635(85.02 - T)$$

where ρ is the density in g/cm³ and T is the temperature in kelvin. This equation gives only poor accuracy if one extrapolates to beyond 77 K.

The density of saturated liquid fluorine along the vapor–liquid coexistence boundary was measured more accurately by the US National Bureau of Standards and the data are now considered the most accurate because they were also normalized based on the International Practical Temperature 1968 Scale [81].

The very accurate experimental density data consisting of 97 data points can be represented by the following equation, which provides a smooth transition to the gas density in proximity of the critical point:

$$[(\rho - \rho_c)/\rho_c] = B_1 Z^{0.35} + \sum_{i=2}^6 B_i Z^{i-1}$$

where $Z = 1 - (T/T_c)$ and the following constants apply for B_1 through B_6 :

$$B_1 \quad 1.81881076$$

$$B_2 \quad 8.75236491\text{E-}01$$

$$B_3 \quad -8.50458910\text{E-}01$$

$$B_4 \quad 1.37284761$$

$$B_5 \quad -1.01331503$$

$$B_6 \quad 2.73840128\text{E-}01$$

and the following critical point properties are used to connect the data: $T_c = 144.31$ K, $\rho_c = 15.10$ mol/L = 0.574 g/cm³.

Table 8 in Section 2.4 on compressibility and velocity of sound contains two additional sets of data on the density of liquid fluorine at very high pressures up to 21 MPa.

2.3.3 Equation of State of Gaseous Fluorine

Like all gases, fluorine gas at higher pressures and lower temperatures does not behave as an ideal gas. The intermolecular force constants of gaseous fluorine in the region 80–300 K have been determined from measurements of the second virial coefficients [89]. On the assumption that gas imperfection resulted only from binary collisions of spherical non-polar molecules, the force constants obtained were $r_0 = 3.61 \pm 0.04 \text{ \AA}$ and $\varepsilon_0/k = 121 \pm 3 \text{ K}$. These force constants yielded viscosities that were in good agreement with the experimental data of Kanda if high temperature data points were discarded.

The form of a reduced Helmholtz energy function was used to derive an equation of state that included an equation to represent the behavior of the ideal gas [90, 91]. The coefficients in the equation were determined by a least-squares method where the terms used were selected statistically from a given data bank, thus reducing intercorrelation.

The analytical equation of state of Song and Mason was applied to calculate the compressed and saturation thermodynamic properties of fluorine [92, 93]. It was based on a statistical–mechanical perturbation theory of hard convex bodies and was a fifth-order polynomial in the density. The equation of state has been used to calculate thermodynamic parameters, including the critical constants, the vapor pressure curve, the compressibility factor, the fugacity coefficient, the enthalpy, the entropy, the heat capacity at constant pressure, the ratio of heat capacities, the Joule–Thomson coefficient, the Joule–Thomson inversion curve, and the velocity of sound for fluorine.

Thermophysical properties of fluorine were calculated with the Goharshadi–Morsali–Abbaspour (GMA) equation of state under critical conditions, including density, volumetric, and thermodynamic properties over extended ranges of pressure and temperature [94]. The results showed that the GMA equation of state reproduced the experimental PVT data of fluorine within experimental errors throughout the liquid phase. The calculated results differed only by a few percent from the experimental data.

2.4 Compressibility and Velocity of Sound of Liquid Fluorine

The bulk modulus is the reciprocal of compressibility. Two types of compressibility are generally measured and reported in the literature, the *isothermal* and the *adiabatic* compressibility. The coefficient of thermal expansion α and compressibility β can be calculated from partition functions, which also lead to values for heat capacities at constant volume or constant pressure.

The velocity of sound in liquid fluorine was measured along two isotherms (110 and 130 K) at pressures up to 21 MPa [95, 96]. The uncertainty in the measured velocity of sound data was estimated to be less than $\pm 0.05\%$. The results are summarized in

Table 8, also including density data obtained in a PVT apparatus at the same temperature and pressure.

Table 8: Velocity of sound in liquid fluorine.

Temperature K	Pressure MPa	Density mol/L	Velocity of sound, experimental m/s
130	21.049	33.059	621.6

Data source: [95]

The validity of an approximate equation of state of real fluids and the expression for surface tension of hard-sphere molecules in liquids was tested for the case of fluorine and the results were compared with those measured by other authors [97] (Table 9). The expressions for the pressure coefficient of bulk modulus (C_1) and acoustical parameter (K) can also be derived from the measured surface tension of liquid fluorine. The acoustical parameter K is defined as the ratio of the temperature coefficient of ultrasonic velocity to the thermal expansion coefficient (α). Unfortunately, Sharma [97] was using the obsolete Kanda [98] surface tension data for comparison, which were obtained with impure fluorine and are not reliable.

Because the microscopic adiabatic heating at the knots of standing sound waves can already dissociate some of the fluorine, the propagation and attenuation of sound in fluorine gas is different than that in other gases. Thermal relaxation of sound waves can be used to measure dissociation and recombination kinetics [99]. See also [100, 101].

Table 9: Calculated and measured surface tension and acoustical parameter of liquid fluorine.

Temperature, K	Surface tension, Kanda, N/m	Surface tension, Sharma, N/m	Pressure coefficient of bulk modulus (C1)	Acoustical parameter K

Data source: [98, 97]

2.5 Vapor Pressure of Liquid Fluorine

The vapor pressure of liquid fluorine has been measured by several investigators up to temperatures slightly above the normal boiling point. We provide several curve fits of experimental data, but would prefer the data published by NIST on the ChemWeb web site [102]. Curve fits are useful for interpolation of data but should not be used to extrapolate to temperatures outside their valid range. Table 10 compares measured vapor pressures and calculated data from two different curve fits.

The vapor pressure between 53 and 90 K can be expressed by the following equation [77]:

$$\log p_V = 7.08718 - 357.258/T - 1.3155 \times 10^{13}/T^8$$

where p_V is the vapor pressure in mm Hg and T is the temperature in kelvin. The boiling point derived from this equation is 85.02 ± 0.02 K.

The vapor pressure curve shown in Figure 4 is based on vapor pressure measurements by [78]:

$$\log p_V = 8.3317 - 406.8/T - 0.007785 T$$

where p_V is the vapor pressure in mm Hg and T is the temperature in kelvin.

Figure 5 is a comparison of vapor pressure data from several different sources. The three curves are very close to each other.

After taking 140 data points on three different samples between 68 and 85 K, the curve fits of vapor pressure data resulted in the following equation [103]:

$$\log p_V = 8.7202 - 462.66/T - 0.01656 T + 1$$

where p_V is the vapor pressure in mm Hg and T is the temperature in kelvin. This equation, once referenced on page 294 of [104] was in error by one order of magnitude because the original source had given the pressures in cm Hg instead of mm Hg. This error has now been corrected by adding 1.0 to the $\log p_V =$ equation.

The vapor pressure of liquid fluorine for the temperature range 53.99–143.99 K can be expressed in the form of an Antoine equation based on the Straty and Prydz data [105]:

$$\log_{10} P = 4.02355 - [322.067 / (T - 4.748)]$$

where P is the vapor pressure in bar and T is the temperature in kelvin.

Figure 4: Vapor pressure of liquid fluorine. (Reproduced and modified from [79].)

Figure 5: Vapor pressure of liquid fluorine; combining data from three different sources.

The original data were re-evaluated and after applying an update for the temperature standard scale, and were expressed by the following equation from [81]:

$$\ln(P/P_t) = D_1X + D_2X^2 + D_3X^3 + D_4X(1-X)^{D_5}$$

where $X = [1 - (T_t/T)]/[1 - (T_t/T_c)]$ and the subscripts t refer to the triple point and the subscripts c refer to the critical point. The constants D_1 through D_5 are as follows:

$$D_1 = 7.89592346$$

$$D_2 = 3.38765063$$

$$D_3 = -1.34590196$$

$$D_4 = 2.73138936$$

$$D_5 = 1.4327$$

Figure 6: Vapor pressure of liquid fluorine. (Reproduced and modified from [10].)

$$\begin{aligned}
 T_t &= 53.4811 \text{ K} \\
 P_t &= 2.52 \times 10^{-4} \text{ MN m}^{-2} \\
 T_c &= 144.31 \text{ K}
 \end{aligned}$$

The normal boiling point of liquid fluorine derived from this equation is $84.95 \pm 0.003 \text{ K}$.

In Figure 6, vapor pressure data from three other sources [77, 106, 107] were plotted together on the same scale and compared with results from a curve-fitted polynomial equation. The data fit the curve-fitted solid line quite accurately.

The vapor pressure data reported by [106] and marked as triangles in Figure 6 are now considered unreliable because they were obtained on impure fluorine. They had reported a vapor pressure equation

$$\log p = -(442.72/T) + 9.1975 - 0.013150 T$$

where p is the vapor pressure in mmHg and T is the temperature in kelvin. These data should be ignored. In the same paper, the heat of evaporation was reported as 1970 cal/mol (8.24 kJ/mol) and the heat of fusion as 390 cal/mol (1.63 J/mol).

2.6 Viscosity of Liquid and Gaseous Fluorine

There are two common definitions of viscosity in use, the absolute (dynamic) viscosity μ defined as the force per unit area necessary to maintain a unit velocity gradient at right angles to the direction of flow between two plates a unit distance apart. The SI unit for absolute viscosity is Pa s or N s m^{-2} . One Poise (abbreviated as Ps) corresponds to $0.1 \text{ Pa s} = 1 \text{ g cm}^{-1} \text{ s}^{-1} = 0.001 \times 0.01 \text{ kg m}^{-1} \text{ s}^{-1} = 10^{-5} \text{ kg m}^{-1} \text{ s}^{-1}$. A common but now obsolete unit for dynamic viscosity is centipoise, (cPs); $1 \text{ cPs} = 10^{-3} \text{ N s/m}^2 = 1 \text{ mPa s}$, where mPa is pressure in millipascal (a pressure unit) and s is time in seconds. Viscosity expressed in $\mu\text{g cm}^{-1} \text{ s}^{-1}$ corresponds to 10^{-7} Pa s . The kinematic viscosity σ is defined by

$$\sigma = \frac{\mu}{\rho}$$

where ρ is the density of the incompressible fluid. The common but now obsolete unit for kinematic viscosity is centistokes (cSt); $1 \text{ cSt} = 10^{-6} \text{ m}^2/\text{s} = 1 \text{ mm}^2/\text{s}$. Kinematic viscosity data can be converted back to dynamic viscosity by multiplying with the density:

$$\mu = \sigma \times \rho.$$

The theorem of corresponding states (excess functions) and measured second virial coefficients of the equation of state for fluorine have been used to calculate theoretical viscosities and thermal conductivities for liquid and compressed gaseous fluorine

over a wide range of temperatures and pressures [108]. Tabulated data were presented for temperatures from 70 to 300 K and pressures from 1 to 200 atm, but may be inaccurate by up to 10% at conditions near the critical point. At lower pressures, the agreement with experimental data is modestly good (Figure 7 and 8 [viscosity] and Figure 12 [thermal conductivity]).

2.6.1 Viscosity of Gaseous Fluorine

A torsionally oscillating quartz crystal was used to measure the coefficient of shear viscosity for gaseous fluorine from 155 to 300 K at pressures up to 20 MPa, and for saturated liquid fluorine for temperatures from 70 to 144 K [109]. The accuracy of the results was estimated to be of the order of 2%, with the precision somewhat better, approximately 0.5%. The dependence of the viscosity on density has been investigated by representing the gaseous data along isotherms in power-series expansions. Figure 7 is a comparison of measured and calculated viscosity data for gaseous fluorine. Table 11 is a summary of gaseous viscosity data from two different sources.

Figure 8 shows the viscosity of gaseous fluorine at elevated pressures.

Viscosity and thermal conductivity of fluorine gas in the range 100–2500 K and 0.25–2.0 atm pressure were computed using the Chapman–Enskog first approximation equations for the thermal equilibrium binary mixture of fluorine atoms and molecules [111, 112]. The procedures accounted for inelastic encounters for the fluorine molecules and assignment of the change in rotational collision numbers with temperature. Computed data agreed well with experimental viscosity and thermal conductivity data over

$1 \mu\text{g cm}^{-1} \text{ s}^{-1} = 10^{-7} \text{ Pa s}$

the temperature range where measurements were available. For example, the viscosity at 300 K and 101 kPa was calculated to be $227.1 \times 10^{-6} \text{ g cm}^{-1} \text{ s}^{-1}$.

2.6.2 Viscosity of Liquid Fluorine

Older viscosity and other physical properties data for liquid fluorine from [113], which have been cited by many authors, are not reliable and have since been replaced by more accurate data, as shown in Table 12. Figure 9 shows the measured and calculated viscosity of saturated liquid fluorine as a function of temperature.

Table 13 contains viscosity data for liquid fluorine under pressure at temperatures above its normal boiling point.

Figure 8: Viscosity of gaseous fluorine at elevated pressures. (Reprinted and modified from [109], with permission from © 1974 Elsevier; permission conveyed through RightsLink.)

The viscosity of liquid fluorine can be calculated from the following equation [86, 87]:

$$\eta = 2.43 \times 10^{-4} \exp(194/T)$$

where η is the viscosity in cPs and T is the temperature in kelvin.

The viscosity of liquid fluorine can be calculated from the equation

$$\log \eta = -2.5818 + 1.0170E + 02/T + 1.6489E - 02 \times T - 8.9947E - 05 \times T^2$$

where η is the viscosity in cPs and T is the temperature in kelvin. A sample calculation for $T = 100$ K gives the viscosity as 0.153 cPs [114, 115].

In addition to sea level pressure measurements, the coefficient of shear viscosity of liquid fluorine was measured using a torsionally oscillating quartz crystal for compressed liquid fluorine from 90 to 140 K at pressures up to 20 MPa, and for saturated liquid fluorine for temperatures from 70 to 144 K [109]. The results are illustrated in Figure 10.

Table 12: Viscosity of saturated liquid fluorine at 0.101 MPa.

2.7 Surface Tension of Liquid Fluorine

The surface tension of liquid fluorine is summarized in Tables 14 and 15 and illustrated in Figure 11. Preliminary surface tension data were already shown in Table 9 above.

Table 14: Surface tension of liquid fluorine.

Temperature			Surface tension	
K	°C	°F	dyn/cm	N/m
66.21	−206.9	−340.5	18.85	0.01885
70.26	−202.9	−333.2	17.7	0.0177
70.68	−202.5	−332.4	17.4	0.0174
72.05	−201.1	−330.0	17.02	0.01702
73.35	−199.8	−327.6	16.86	0.01686
75.09	−198.1	−324.5	16.49	0.01649
75.19	−198.0	−324.3	16.28	0.01628
77.15	−196.0	−320.8	15.73	0.01573
79.9	−193.2	−315.9	14.81	0.01481

Data source: [88]

Conversion: $10^5 \text{ dyn} = 1 \text{ N}$; $1 \text{ cm} = 10^{-2} \text{ m}$; $1 \text{ dyn/cm} = 10^{-5} \text{ N/cm} = 10^{-3} \text{ N/m}$

Table 15: Surface tension of liquid fluorine.

Temperature			Surface tension	
K	°C	°F	dyn/cm	N/m
69.2	−204.0	−335.1	17.9	0.0179
71.2	−202.0	−331.5	17.4	0.0174
73.2	−200.0	−327.9	16.7	0.0167
75.3	−197.8	−324.1	16.2	0.0162
76.4	−196.7	−322.2	15.9	0.0159
78.2	−195.0	−318.9	15.4	0.0154
81.0	−192.2	−313.9	14.6	0.0146

Data source: [86, 87]

Conversion: $10^5 \text{ dyn} = 1 \text{ N}$; $1 \text{ cm} = 10^{-2} \text{ m}$; $1 \text{ dyn/cm} = 10^{-5} \text{ N/cm} = 10^{-3} \text{ N/m}$

Surface tension can be expressed by the McLeod equation:

$$\gamma^{1/4}/(D_{\text{Liq}} - D_{\text{Gas}}) = 1.276 \pm 0.002$$

where $D_{\text{Liq}} - D_{\text{Gas}}$ is liquid density minus the vapor density and 1.276 is the McLeod constant which appeared to be constant to within $\pm 0.06\%$ for the entire temperature range investigated.

Figure 11: Surface tension of liquid fluorine, data from two different sources.

Table 16: Surface tension of liquid fluorine.

Temperature	Surface tension	
K	N/m	dyn/cm
61.41	0.0138	13.85
65.30	0.0132	13.17
71.00	0.0122	12.20
81.50	0.0104	10.41

Data source: [98]

Surface tension data from two different sources are compared in Figure 11 with an exponential fit of the experimental data. Older surface tension data for fluorine shown in Table 16 are less reliable [116].

2.8 Thermal Conductivity of Gaseous and Liquid Fluorine

The thermal conductivity of gaseous fluorine increases with temperature, whereas the thermal conductivity of liquid fluorine decreases with temperature. A similar trend is observed for oxygen. The theorem of corresponding states (excess functions) and measured second virial coefficients of the equation of state for fluorine have been used to calculate theoretical thermal conductivities for liquid and compressed gaseous fluorine over a wide range of temperatures and pressures [108]. Tabulated data were presented for temperatures from 70 to 300 K and pressures from 1 to 200 atm, but may be inaccurate by up to 10% at conditions near the critical point. At lower pressures, the agreement with experimental data is modestly good (Figure 12).

Figure 12: Measured and calculated thermal conductivity of gaseous fluorine. (Chart created by Schmidt 2016 based on data from [108].)

Assuming a heat of dissociation of 167 to 209 kJ/mol (40 to 50 kcal/mol), the difluorine molecule should already be dissociated into atoms at 873 K and 101 kPa (600 °C and 1 atm) to an extent of about 0.1 to 1%. Therefore, if thermal conductivity measurements extend to that temperature, the dissociation of difluorine molecules at the hot end and the recombination of fluorine atoms at the cold end contribute to the purely physical heat transfer through sensible heat and convection.

2.8.1 Thermal Conductivity of Gaseous Fluorine

The thermal conductivity of gaseous fluorine was measured by a hot wire method using a resistance-heated nickel wire [117, 118]. Complications arose as soon as the nickel wire reached higher temperatures and became coated with a layer of nickel fluoride. The λ values measured at the highest temperature (788 K = 515 °C), however, taking into account their range of uncertainty, fit into the curve to be expected for “normal” (no dissociation) thermal conductivity. At this temperature a total of 12 measurements with fluorine were carried out in the pressure range 50 to 340 mm Hg, and yield the mean value

$$\lambda \text{ (at 788 K = 515 °C)} = 1.46 \pm 0.06 \times 10^{-4} \text{ cal cm}^{-1} \text{ s}^{-1} \text{ °C}^{-1}$$

A pronounced dependence on total pressure, as would be expected by the influence of dissociation, was not observed in this measurement. This experiment was conducted as part of an effort to determine the heat of dissociation of difluorine, and the results speak against values smaller than 180 kJ/mol (43 kcal/mol) for this property.

A pure sample of fluorine needed for the determination of thermal conductivity was prepared by decomposition of chlorine trifluoride. The thermal conductivity of

fluorine gas was then measured at temperatures up to 800 K [119]. A Nernst formula was used to calculate the theoretically to be expected temperature dependence of the thermal conductivity, based on the degree of dissociation predicted for different temperatures. A comparison of the measured temperature dependence of the thermal conductivity for N_2 , O_2 , and F_2 showed that the three gases behaved very similarly between 100 and 800 K. There was no indication of excessive dissociation in the case of F_2 . Also, even at the highest experimental temperature, the thermal conductivity of difluorine was independent of pressure. For comparison, with iodine vapor, which has a lower dissociation energy (148 kJ/mol = 35.4 kcal/mol), the increase in thermal conductivity due to dissociation was quite measurable.

The temperature dependence of thermal conductivity of a dissociating gas is determined by the speed at which a dissociation equilibrium establishes itself in the gas phase and at the interphase with the hot surface that provides the energy for the dissociation. A function was derived for difluorine that predicts the temperature dependence of thermal conductivity of F_2 with the aid of the relaxation time and a coefficient of accommodation [120]. Although the measurements and predictions agreed well with each other for bromine vapor, the lack of a dissociation effect on the thermal conductivity of F_2 at temperatures up to 973 K (700 °C) was blamed on the inadequate rate of reaction in the gas phase and a very small coefficient of accommodation (10^{-4} to 10^{-3} ; Table 17). The coating of the hot wire with nickel fluoride also interfered with some of the measurements.

Table 17: Thermal conductivity of gaseous fluorine.

Temperature, K	Thermal conductivity	
	$\text{cal cm}^{-1} \text{s}^{-1} \text{K}^{-1} \times 10^7$	$\text{W cm}^{-1} \text{K}^{-1} \times 10^7$

2.8.2 Thermal Conductivity of Liquid Fluorine

Figure 13 is a comparison of measured and calculated data for the thermal conductivity of liquid fluorine. For data on the thermal conductivity of liquid fluorine see also [121].

Figure 13: Measured and calculated thermal conductivity of saturated liquid fluorine. (Chart created by Schmidt 2016 based on data from [108].)

Triangles represent measured data from an inaccessible source (Smith, Ohio State University)

2.8.3 Heat Transfer Coefficient of Liquid Fluorine

Measuring the heat transfer from injectors or vaporizers to liquid fluorine requires extreme precaution and careful design of the experiment [122]. Only a few materials are resistant to hot and flowing fluorine. Incorrect choice of materials for this experiment could cause leakage and ignition accidents. Fluorine cannot be used for regenerative cooling of rocket engines [123].

2.9 Critical Constants of Fluorine

Table 18 lists the critical constants for fluorine [124].

Table 18: Critical point data for fluorine.

T_c , K	p_c , atm	ρ_c , g/cm ³	References
144.16	55		[79]
144.31	51.47	0.574	[82]
144	55		[78]

2.10 Solubility, Miscibility, and Solutions of Liquid Fluorine

The solubilities of various compounds in liquid fluorine are summarized in Table 19. The most troublesome contaminants in liquid fluorine are those that are insoluble and are carried along in particulate form, clogging filters and injection orifices.

Table 19: Solubility of fluoride compounds in liquid fluorine.

Material	Solubility at 77 K = -196 °C = -320 °F, mol percent
Carbon tetrafluoride	87.5
Oxygen difluoride	10.0
Silicon tetrafluoride	<0.05
Hydrogen fluoride	<0.5
Sulfur hexafluoride	<0.1
Nitrogen trifluoride	0.12
Hexafluoroethane	2.87
Perchloryl fluoride	0.33

Data source: [125]

Additional contaminant solubility data are contained in [66]. Chlorine will initially dissolve in liquid fluorine, but when the mixture thaws, the two gases will begin to react, forming ClF and ClF₃ [67]. A special apparatus was devised for the purpose of taking a sample of the mixture for analysis, and used in the analysis of liquid air and a solution of chlorine in liquid fluorine.

Data on the solubility of fluorine gas in various fluorocarbons and concentrated acids are contained in [126].

Solubilities of several substances in liquid fluorine were determined, such as carbon tetrafluoride (CF₄), perfluoroethane (C₂F₆), perchloryl fluoride (ClO₃F), nitryl flu-

oride (NO_2F), silicon tetrafluoride (SiF_4), boron trifluoride (BF_3), tetrafluoroethylene polymer, cobalt trifluoride (CoF_3), and aluminum trifluoride (AlF_3) [127]. In addition, the liquid–liquid systems nitrogen/fluorine (N_2/F_2) and nitrogen trifluoride/fluorine (NF_3/F_2) were investigated. All solutions were studied within the temperature range 68 to 83 K by vapor–pressure measurements. The NF_3/F_2 system behaved as a nearly ideal solution throughout the entire composition range of 0 to 100% NF_3 as determined by vapor–pressure measurements between 68 and 78 K. The nitrogen/fluorine system was completely miscible at 77.5 K. Powdered tetrafluoroethylene polymer, SiF_4 , BF_3 , CoF_3 , and AlF_3 were all less soluble than could be determined by the experimental apparatus used.

2.11 Thermodynamic Properties of Liquid and Gaseous Fluorine

Thermodynamic properties of fluorine summarized in this section and Table 20 through Table 23 are heat capacity, enthalpy of formation, entropy of formation, and enthalpies involved with phase changes. The heat of dissociation of difluorine has been uncertain for a long time, and has had some influence on the thermodynamic property data measured and calculated for many other fluorine compounds. In order to calculate theoretical specific impulse of a rocket propellant, thermodynamic data are needed not only for rocket propellants that go into the combustion chamber but also for combustion products that flow out through the nozzle. Thermodynamic data for HF (and DF, a chemical laser product) have also received a lot of attention and are equally important [128].

For entropies, it is common practice to give the values in “entropy units”, abbreviated as “e.u.”. One e.u. is $1 \text{ cal g}^{-1} \text{ K}^{-1}$.

One book chapter contains a summary of information on the dissociation energy of difluorine, the heat of formation of HF, fluorine bomb calorimetry at constant volume, and various other types of calorimetry for the determination of thermochemical properties of fluorine compounds [130].

Bibliographic information on physical property data for difluorine between 0 and 300 K collected from 51 references is given in [131].

Thermodynamic functions of fluorine that were first published in 1939 were later revised based on the availability of more accurate electron diffraction and Raman spectra [132]. The molar heat capacity at 298 K was $31.24 \text{ J mol}^{-1} \text{ K}^{-1}$ ($7.466 \text{ cal mol}^{-1} \text{ }^\circ\text{C}^{-1}$).

Thermodynamic functions of fluorine were included in a review of the status of mathematical models and correlations for the calculation of thermodynamic properties of cryogenic fluids [133]. This review included references to the original works that contain details of the mathematical models and correlation methods, and provided sources of information about using the computer formulations for applications and Internet access to computer programs for thermodynamic properties of the fluids.

Table 20: Thermodynamic properties of difluorine.

Thermodynamic properties of fluorine are summarized in Table 20 through Table 23.

The data published by [134] and summarized in Table 22 were criticized for containing small errors scattered throughout because the relation $(F^0 - H^0)/T = (H_0^0 - H_0^0)/T - S^0$ was not always satisfied [128]. A new set of calculations was based on improved spectroscopic data for HF(G) and DF(G) and thermophysical data for F and F₂ were tabulated for temperatures from 298 to 5000 K in 100-K increments (Table 23).

An apparatus to measure vapor pressure and PVT data of fluorine from the triple point to 300 K at pressures up to about 24 MPa was constructed and used to measure PVT data of fluorine [135]. A network of isotherm and isochore polynomials and a truncated virial equation were used to represent all PVT data. Additional comparisons were made to measure specific heats and latent heats of vaporization. Extensive tables of thermodynamic properties of fluorine included pressure, temperature, density, isotherm and isochore derivatives, internal energy, enthalpy, entropy, specific heats at constant pressure, and volume and velocity of sound. Some erroneous values for the internal energy and enthalpy of the compressed liquid below 135 K, published previously, had to be corrected in a revision.

Accurately measured PVT and specific heat data were then used to calculate thermodynamic functions of gaseous and liquid fluorine up to pressures of 21 MN/m² = 21 MPa (1 MN/m² = 9.86923 atm) and temperatures between 50 and 310 K [136, 137].

2.11.1 Heat Capacity of Solid, Liquid, and Gaseous Fluorine

2.11.1.1 Heat Capacity of Solid Fluorine

When measuring the heat capacity of solid fluorine between 14 and 85 K, it was noticed that a phase transition took place that documented itself in a sudden increase in heat capacity [77]. The phase transition took place at 45.55 ± 0.02 K, with an enthalpy change of $728 \text{ J/mol} = 173.90 \pm 0.04 \text{ cal/mol}$. Similar phase transitions have been observed with solid nitrogen and solid oxygen. At the phase transition temperature, an anharmonic torsion oscillation changes into a not totally free, somewhat hindered rotation of the molecule.

2.11.1.2 Heat Capacity of Liquid Fluorine

Experimental specific heats of fluorine at constant total volume were measured for the two-phase, liquid vapor system from the triple to the critical point. The constant volume heat capacity of two-phase liquid fluorine was measured at five different loading densities ranging from 6.77 to 34.10 mol/L [138]. Specific heats of liquid along the two-phase saturated liquid coexistence path were derived by the use of PVT data for the two-phase system, and were represented by a formula to facilitate computations of thermodynamic properties. The subscript σ stands for the saturated two-phase condition. Figure 14 shows $C_{V\sigma}$ for the liquid on the path along the saturation line. On the scale of this plot, the data appear to be linear in temperatures below boiling point (85 K).

Figure 14: Heat capacity of two-phase liquid fluorine along the saturation line. (Reproduced and modified from [138].)

Specific heat along the saturation (coexistence) path of T ; P conditions can be expressed by the equation

$$C_{v\sigma} = C_v - \frac{T_a}{\rho} \left\{ \frac{1}{\rho} \frac{d\rho}{dT} \frac{dP}{dT} + \left[\frac{\rho V_b}{N_b} - 1 \right] \frac{d^2P}{dT^2} \right\}$$

where $C_{v\sigma}$ is the heat capacity at saturation, T_a is the average temperature of the temperature interval over which C_v was measured, ρ is the density, V_b is the volume of the calorimeter bomb, and N_b is the gram mols of fluid in the bomb.

2.11.1.3 Heat Capacity of Gaseous Fluorine

The gas phase heat capacity, excess enthalpy, and standard entropy can be calculated from the following polynomial equations (Shomate Equation). The constants are given in Table 24 below.

$$\begin{aligned} C_p^\circ &= A + B\tau + C\tau^2 + D\tau^3 + E/\tau^2 \\ H^\circ - H^\circ_{298.15} &= A\tau + B\tau^2/2 + C\tau^3/3 + D\tau^4/4 - E/\tau + F - H \\ S^\circ &= A \times \ln(\tau) + B\tau + C\tau^2/2 + D\tau^3/3 - E/(2\tau^2) + G \end{aligned}$$

where C_p is the heat capacity in $\text{J mol}^{-1} \text{K}^{-1}$, H° is the standard enthalpy in kJ/mol , S° is the standard entropy in $\text{J mol}^{-1} \text{K}^{-1}$, and τ is the fractional temperature in $\text{K}/1000$. The constants in Table 24 are valid for a temperature range from 298 to 6000 K.

Data source: [76, 129]

The single-phase heat capacity of fluorine at constant volume was measured over a wide range of temperatures, 80 to 300 K, pressures up to 23 MPa, and loading densities up to 26.3 mol/L [139]. For a wide range of densities about the critical isochore, the specific heat increased sharply as the temperature approaches the two-phase envelope, which was to be expected. At densities far removed from the critical, the temperature dependence was relatively weak. A graph showed isochores of heat capacity versus temperature for six different loading densities between 6.5 and 26.3 mol/L.

2.11.2 Enthalpy of Formation of Liquid and Gaseous Fluorine

2.11.2.1 Enthalpy of Dissociation

Because of the difficulty in determining the heat of dissociation of the difluorine molecule into atomic fluorine, the thermodynamic data given for atomic fluorine in the literature vary substantially. It is difficult to determine the heat of dissociation of difluorine from spectroscopic data because the spectrum does not show discrete ground states. Instead, it shows a continuous absorption band that stretches from 2300 to 3500 Å. There has been a controversy raging over several decades about which enthalpy of dissociation data of difluorine should be used to calculate the derived thermodynamic functions. The data seemed to be very dependent on the method used for their determination. Several research groups attacked this problem, but their results did not agree. The heat capacity C_p , enthalpy function H/T , and entropy S_0 for the free F atom was calculated based on the enthalpy of dissociation for difluorine that had been determined earlier [140].

Spectroscopic and thermal data cast doubt about the heat of dissociation of fluorine, which at one time was reported to be as high as 251 kJ/mol (60 kcal/mol). The thermal conductivity of difluorine gas was measured and found to be almost identical to that of dinitrogen, which indicated that no dissociation occurred and led to the erroneous assumption that the heat of dissociation was very high. Renewed interpretation of the absorption spectrum indicated that the lower value was more accurate [141].

For a long time the first published value for the dissociation energy of difluorine (239 kJ/mol = 57.2 kcal/mol) was considered a reliable data point. Other sources gave 268 kJ/mol = 64 kcal/mol. Until 1954, a dissociation energy of 156 kJ/mol = 37.4 kcal/mol was considered reliable, but that assumption was quickly proven wrong. Table 25 shows a compilation of data for the dissociation energy of difluorine, determined by different methods and leading to different results.

Using a method first described by [118], who estimated the value to be between 40 and 50 kcal/mol, the dissociation energy of difluorine was determined using an explosion method in a closed bomb and found to be 154.8 ± 8 kJ/mol = 37.0 ± 2 kcal/mol [153].

Dissociation and recombination kinetics are often studied by monitoring the decay of dissociation products behind a shock wave in a shock tube. This method was used by several other investigators to measure the heat of dissociation of fluorine [154, 155].

Doescher's method consisted essentially in directly comparing the pressure variation with temperature of a quantity of fluorine and that of a quantity of nitrogen. Twenty-four determinations of the equilibrium constant were made, and $\ln K$ was plotted as a function of reciprocal absolute temperature, giving the activation energy of the dissociation [156].

The convergence boundary of the vacuum UV absorption bands of the F_2 molecule was used to derive a dissociation energy of 135.1 ± 9.6 kJ/mol = 32.3 ± 2.3 kcal/mol [157–

^a Data sorted by ascending dissociation energy values

159]. For most other dissociating polyatomic gases one can use the more energetic (toward shorter wavelengths) edge of the absorption band as an indication of beginning dissociation by photolysis. For fluorine, this method does not give the expected results [160].

The dissociation of <1% F₂ in Ar, Kr, or Ne in a shock tube was studied over a range from 1665 to 2670 K and the temperature dependence of the rate constants used to calculate the heat of dissociation [142]. Rate constants were determined from both fluorine molecule and atom analysis in mixtures containing 1% F₂ or less. The activation energy was 113 kJ/mol = 27 kcal/mol. See also Eucken and Wicke [117], Evans et al. [161], Gaydon [162], and Sanderson [163].

Altogether, the dissociation energy of difluorine is much lower than one would expect by extrapolation from the dissociation energies of the other halogens. This number has to be known accurately to predict flame temperatures for fluorine flames and to predict the performance of fluorine and non-metallic fluorides as rocket propellants.

For a direct determination of the heat of dissociation of difluorine the gas effusion method is particularly suitable as the measurements are performed at low pressures (molecular-flow region) and therefore a measurable degree of dissociation is attained at relatively low temperatures [150]. The rate of gas effusion was determined over the temperature range from 500 to 800 K at a total pressure of 4×10^{-4} mm Hg. The results of these measurements yield for the reaction

a value of $\Delta H_{\text{diss}} = 157 \pm 3.3 \text{ kJ/mol} = 37.6 \pm 0.8 \text{ kcal/mol}$.

2.11.2.2 Enthalpy of Formation of Gaseous and Liquid Fluorine

The enthalpy of formation of gaseous difluorine under standard conditions is by definition zero. The enthalpy of formation data for liquid difluorine collected from different literature sources are summarized in Table 26.

Table 26: Enthalpy of formation data for liquid fluorine.

Molecular mass of F₂: 37.9968 g/mol (IUPAC 1962)

The high specific impulse of fluorine with hydrogen or hydrogen compounds is based on the high enthalpy of formation of HF. This number must be known very precisely so that the theoretical rocket performance can be calculated accurately. The US National Bureau of Standards [169] has developed a calorimeter that can be used to determine the heat of reaction of fluorine with other gases, for instance, ammonia.

2.11.3 Enthalpy of Fusion and Solid-State Phase Transitions of Solid Fluorine

Enthalpy of fusion data for solid fluorine are summarized in Table 27.

Molecular mass of F₂: 37.9968 g/mol (IUPAC 1962)

Solid fluorine can exist in two different phases, α -F₂ and β -F₂. Physical properties such as the heat of fusion or the heat of sublimation depend on the type of phase existing at the moment of melting or sublimation.

The heat of fusion data reported by [170] were unfortunately obtained on impure fluorine and are not very accurate.

2.11.4 Enthalpy of Vaporization of Liquid Fluorine

The heat of vaporization of liquid fluorine (and any other liquid) is determined most often by the Clausius–Clapeyron equation rather than through direct calorimetric measurements. Data from various sources are summarized in Table 28.

^a calorimetric data

2.11.5 Heat of Mixing of Liquid Fluorine

The heat of mixing of liquid fluorine and liquid oxygen is minimal and not measurable. Therefore, the enthalpy of formation of fluorine–oxygen (FLOX) is assumed to be additive without heat of mixing.

2.11.6 Entropy of Liquid Fluorine

Values calculated from spectroscopic data [134, 172], (39.56 ± 0.01 and 39.62 ± 0.02 e.u., respectively) were in good agreement with the calorimetric value (39.58 ± 0.16 e.u.) [77].

The National Institute of Standards and Technology (NIST) WebBook data base gives the entropy of the ideal gas at 1 bar as $202.791 \pm 0.005 \text{ J mol}^{-1} \text{ K}^{-1}$ and the source is a Committee on Data Review value [173]. An alternative value found in the literature is $202.80 \text{ J mol}^{-1} \text{ K}^{-1}$ from the NIST/Joint Army, Navy, Air Force (JANAF) Tables [129]. The entropy of vaporization was calculated to be 18.427 e.u. [174], in good agreement with measured data 18.378 e.u. from [77]. See also [175, 176].

2.12 Molecular Structure of Liquid Fluorine

A better understanding of the molecular structure of gaseous, liquid, and solid fluorine will be useful in predicting thermodynamic and other physical properties of this rocket propellant oxidizer.

Another method of analyzing the experimental atom–atom pair distribution functions based on the corresponding state principle has been applied to liquid fluorine to explain the large discrepancies found when comparing experimental and simulated molecular interaction forces as a function of intermolecular distance [177]. The microscopic structure of liquid fluorine must be very different from that of other liquid halogens. The interatomic distance of fluorine atoms in the difluorine molecule in the vapor state is $1.435 \pm 0.010 \text{ \AA}$ [178].

Measurements of the neutron scattering static structure factor $S(Q)$ of orthobaric liquid fluorine at 77 K and the atom–atom correlation function were compared with those of other halogens and oxygen [179]. From the $d = f(r)$ pair distribution function it was shown that liquid fluorine has a coordination number of first neighbors more similar to that of liquid oxygen than other halogens. The number of atoms in the first and second coordination shell is in good agreement with a closely packed arrangement of atoms.

2.12.1 Electron Affinity

Because fluorine was thought to be the most electronegative of the elements, along with its high oxidative powers, the electron affinity of fluorine has undergone extensive investigation. This property is important in calculating thermodynamic data for fluorine atoms, ions, and molecules, and, ultimately, calculating the performance of fluorine as a rocket propellant. The tendency to complete the second shell with eight electrons is the driving force for the extreme chemical activity of fluorine (known as the octant rule). This gives fluorine the highest electronegativity, with a potential of -2.85 V , compared with -1.36 V for chlorine and -1.22 V for oxygen. At the first glance, electron affinity appears to be a property of mostly academic interest, but when looked at more closely, it is one of the driving forces behind the reactivity of fluorine and the polarity of chemical bonds in the structure of fluorine compounds.

The electron affinity, E_{ea} , of an atom or molecule is the energy required to detach an electron from a singly charged negative ion such as would occur in the following process:

An alternative definition is the energy released ($E_{\text{initial}} - E_{\text{final}}$) when an electron is attached to a neutral atom or molecule. It should be noted that the sign convention for E_{ea} is the opposite to most thermodynamic quantities: a positive electron affinity indicates that energy is released on going from atom to anion. All elements have a positive electron affinity. Atoms whose anions are relatively more stable than neutral atoms have a smaller E_{ea} . When comparing the electron affinities of the halogens, it is surprising to note that the gradual increase in the group from iodine (295 kJ/mol) over bromine (343 kJ/mol) to chlorine (349 kJ/mol) is disrupted when going from chlorine to fluorine. All of a sudden, the electron affinity drops instead of increasing further. The commonly accepted value for fluorine is 328 kJ/mol . Of all the elements, chlorine most strongly attracts extra electrons.

Table 29 gives a summary of publications on the electron affinity of fluorine that relate to its reactivity in many oxidation reactions.

Table 29: Summary of publications on the electron affinity of fluorine.

2.12.2 Other Thermodynamic Data

Additional physical and thermodynamic properties of difluorine and the fluorine atom and on the electron affinity of the F atom, the refractive index, viscosity, the electrical polarization, and the diameter of the F_2 molecule are described in [140]. That paper also contains data on thermal conductivity and the rate of dissociation of gaseous difluorine.

When designing a rocket engine running on liquid fluorine as the oxidizer, it helps to know the ease of atomization, the rate of evaporation and the mean droplet size of liquid fluorine. These numbers enter into calculations for the necessary L^* of a rocket engine. Next to liquid oxygen, liquid fluorine was one of the propellants that evaporated the fastest [183]. Other propellants investigated in this study were O_2 , $n\text{-}C_7H_{16}$, NH_3 , and N_2H_4 .

The performance of fluorine as a rocket propellant has to be calculated from accurate thermodynamic data for both the reactants and the combustion products. All propellant combinations with fluorine as the oxidizer have HF as a combustion product. In the liquid state under standard conditions at 298 K, HF is associated and its formula is H_2F_2 .

The enthalpy of formation of liquid H_2F_2 was measured using a bomb calorimeter and measuring the heat released during the combustion of H_2 gas in F_2 gas. The standard molar enthalpy of formation of liquid HF ΔH_f° (HF, L) was found to be $-303.56 \pm 0.27 \text{ kJ mol}^{-1}$ at $T = 298.15 \text{ K}$ and $p_o = 101.325 \text{ kPa}$ by direct reaction of gaseous hydrogen and fluorine in a bomb calorimeter [184]. The enthalpy of formation of monomeric ideal gas HF under standard conditions is $-272.5 \text{ kJ/mol} = -65.14 \text{ kcal/mol}$.

2.12.3 Molecular Orbital Calculations of Molecular Structure of Liquid Fluorine

Two difluorine molecules may associate in the liquid state to form a dimer $(F_2)_2$ that affects the density and compressibility of the liquid. Two possibilities for the potential energy surface of the $(F_2)_2$ dimer were constructed on the basis of *ab initio* calculations [185]. The best estimate of the complete basis set limit of interaction energy was derived for analysis of basis set incompleteness errors. The most stable structure of the dimer was obtained at $R = 6.82 \text{ au}$, $\theta_a = 12.9^\circ$, $\theta_b = 76.0^\circ$, and $\varphi = 180^\circ$, with a well depth of $716 \mu\text{Eh}$. Two other minima were found for canted and X-shaped configurations. The quality of potentials was tested by computing values of the second virial coefficient, which was supposed to give a more reasonable agreement with experimental values.

2.12.4 Molecular Orbital Calculations of the Molecular Structure of Solid Fluorine

It is unlikely that solid fluorine will ever be used as a rocket propellant, but the properties of solid fluorine are included here nevertheless because they affect the thermodynamic properties of liquid fluorine. Solid fluorine can exist in two different phases, $\alpha\text{-}F_2$ and $\beta\text{-}F_2$. Physical properties such as the heat of fusion or the heat of sublimation depend on the type of phase existing at the moment of melting or sublimation. $\alpha\text{-}$

Fluorine has a regular pattern of molecules and is a crystalline solid, but its molecules do not have a specific orientation. β -Fluorine molecules have fixed locations and minimal rotational uncertainty, which affects the specific heat. Solid fluorine was reported to undergo a transition at 45.55 K with a heat of transition of 728 J/mol = 173.9 cal/mol.

The equilibrium structure and orientations of solid fluorine were calculated by optimizing a general monoclinic lattice with two molecules per unit cell [186]. In addition to the lattice parameters and orientations, the molar volume, sublimation energy, and gas phase second virial coefficients were calculated. Both the proposed $C2/c$ and $C2/m$ structures were found, for which nearly identical sublimation energies were calculated. The quadrupole moment θ was assumed to be 0.65×10^{-26} esu cm² in this work. Pressurizing solid fluorine up to 100 kbar will not bring about any new phases [187].

One e.u. is 1 cal g⁻¹ K⁻¹. Solid fluorine has a normal entropy of fusion (2.28 e.u. = 9.54 J g⁻¹ K⁻¹ = 362 J K⁻¹ mol⁻¹) and has a first-order solid-state transition at about 8 K below its melting point. This indicates that fluorine probably rotates in the solid state at melting point. The significant structure theory of liquids can be applied to calculate physical and thermophysical properties of liquid fluorine in comparison to better investigated liquids such as liquid nitrogen [174]. This theory is based on partition functions and accurately predicts entropy of vaporization, vapor pressure, density, heat capacity, and surface tension to within $\pm 5\%$. The agreement between calculated and observed properties for fluorine was satisfactory. The largest deviations occurred in the comparisons with the critical point and the heat capacity, both of which involved higher-order differentials of the partition function.

The crystal structure of α -fluorine, stable below 45.6 K, has been investigated from XRD patterns [188]. Alpha fluorine is monoclinic, probably space group $C2/m$, but space group $C2/c$ cannot be ruled out completely. There are four molecules per unit cell. At 23 K, the cell dimensions were found to be: $a = 5.50 \pm 0.01$ Å, $b = 3.28 \pm 0.01$ Å, $c = 10.01 \pm 0.01$ Å, $\beta = 134.66 \pm 0.02^\circ$. The unit-cell volume at 23 K was 128.4 Å³, the calculated density was 1.97 g/cm³ and the calculated molar volume was 19.3 cm³/mol. The structure of solid fluorine is very similar to that of α -O₂, the main difference being that the molecules are tilted, probably only by about 11° to alternate sides of the normal to the basal plane in alternate layers, leading to a doubling of the unit cell in the c direction compared with α -O₂.

A re-interpretation of the XRD powder pattern reported by Meyer, Barrett, and Greer concluded that the space group is $C/2c$, with eight F in the unit cell, cell dimensions $a = 5.50$ Å, $b = 3.28$ Å, $c = 7.28$ Å, $\beta = 102.17^\circ$, with $x = 0.285$, $y = 0.317$, $z = 0.0997$ [189].

Reasonable agreement of the calculated external vibration frequencies for solid α -F₂ with observed Raman and far IR spectra was obtained for the $C2/m$ structure [190]. On the basis of those calculations, an assignment of each Raman and far IR band was made, which was consistent with the observed Raman intensities. However, a unique assignment could not be made for the intramolecular Raman bands.

A molecular dynamics simulation study of the ordered and disordered phases of crystalline F_2 calculated several macroscopic and microscopic equilibrium properties at different temperatures, including orientational probability functions of molecules in both crystalline phases [191]. Dynamical properties were analyzed by calculating several auto- and cross-correlation functions at different temperatures and their characteristic times were given in comparison with several other theoretical models. Similar molecular dynamics simulation techniques were then applied to study the monoclinic and cubic phases of crystalline F_2 [192].

2.13 Optical, Electrical, and Magnetic Properties of Liquid Fluorine

Optical properties can be used to determine the purity of fluorine samples. Absorption spectra provide information on the energy levels and bonding states in the molecule.

2.13.1 Absorption, Emission, and Fluorescence Spectra of Liquid Fluorine

2.13.1.1 UV/Visible Absorption Spectra of Fluorine

The visible and UV absorption spectrum of fluorine gas was determined over the range 2100 to 800 Å [193]. A single broad absorption peak was observed with a maximum molar absorptivity of $6.0 \text{ L mol}^{-1} \text{ cm}^{-1}$ at a wave length of 2845 Å. Beer's law was obeyed over a pressure range of 10 to 100 kPa (80 to 760 mm Hg) pressure. Increasing the temperature to 373 K (100 °C) caused only a slight decrease in the absorption, which was within the experimental error arising from more rapid etching of the cell windows. The absorption at 2845 Å appears to be consistent with the pale yellow color of fluorine, and it falls into place in the trend of the colors of the halogens in the periodic table of elements.

The continuous absorption spectrum of molecular fluorine and the Raman displacement for the $0 \rightarrow 1$ vibrational transition have been used to compute the potential energy curve for the repulsive $^1\Pi_u$ state dissociating to two normal fluorine atoms [147]. This curve was consistent with a value of $37.1 \pm 0.85 \text{ kcal/mol}$ for the dissociation energy of the ground state. A weak absorption, attributed on the grounds of location and intensity to $^3\Pi_0^+ \leftarrow ^1\Sigma_g^+$, has been shown to occur in the long wavelength region of the main absorption and a segment of the potential energy curve for $^3\Pi_0^+$ has been deduced. Absorption curves, calculated from the potential energy curves and the ground-state anharmonic eigenfunctions, matched the observed data satisfactorily.

The absorption spectrum of F_2 has been observed in the vacuum-UV region using a special windowless absorption apparatus and a Lyman discharge light source in combination with a 1-m normal incidence spectrograph [149]. A Rydberg series established the photoionization potential of F_2 as 15.7 eV. From a progression of bands at 874 Å, one can deduce the dissociation energy of fluorine as $156.9 \pm 8.4 \text{ kJ/mol} =$

37.5 ± 2 kcal/mol. The binding energy of F_2^+ is 3.3 eV. The low value of the ionization potential was consistent with the observed low value of the dissociation energy. See also Bresler and Shtilerman [194].

The vacuum-UV absorption spectrum of molecular difluorine has been observed at wavelengths below 1500 Å, at a dispersion of 3.75 Å/mm [144]. Spectra have been observed at pressures from 80 to 600 μm Hg and at temperatures both somewhat below 293 K = 20 °C and at approximately 373 K = 100 °C. Previously observed spectra in the vacuum-UV region have been re-interpreted and extended to a wider range. The spectroscopic determination of the fluorine dissociation energy based on a previously identified progression of bands at 877 Å was used to fix a minimum value for the F_2 dissociation energy of 138.3 kJ/mol = 33.05 kcal/mol. Rydberg series converging to the first ionization potential of F_2 have been established and the current data were compared with those of previous studies in the UV region and data from photoelectron spectroscopy to reinterpret data on F_2^+ . Looking at the binding energies of the “ π ” molecular orbitals, some evidence suggested that participation of the “ π ” molecular orbitals may actually be more important than previously acknowledged.

The absorption spectra of liquid F_2 , NF_3 , N_2F_4 , CF_4 , BF_3 , and SF_6 have been measured at low temperatures in the near UV region of the spectrum [195]. It was shown that the liquid-phase absorption spectra did not differ much from the spectra in the gaseous phase. Therefore, the elementary absorption event was characterized by the cross section of photon absorption by an individual molecule. The absorption cross sections of these molecules were represented in the liquid phase, which did not differ significantly from absorption cross sections of these molecules in the gaseous phase. The dependence of the absorption cross sections of liquid fluorine on its concentrations in solutions in LN_2 , Ar, NF_3 , or LOX at 77 K = -196 °C has been studied.

When the absorption spectrum of molecular difluorine in the spectral range between 200 and 400 nm was re-measured, excellent agreement with the published spectrum above 250 nm was found, but below that wavelength the observed absorption was less than in the earlier measurements [196].

2.13.1.2 Infrared Absorption Spectra of Fluorine

Far IR and Raman spectra of crystalline fluorine have been obtained in both solid phases [197]. As expected for the disordered higher temperature form, only the Raman-active stretching fundamental was observed for β - F_2 . Near ~20 K α - F_2 exhibited the following spectral features (in cm^{-1}): Raman $\nu(1-0)$ 985; $\nu(2-0)$ 1764; ν (libration) 44, 55, 77, (93?); Infrared ν (translation) 28, 42.5, 80. The predictions of a preliminary calculation of the optically active lattice frequencies for the low-temperature phase were in poor agreement with the observed lattice frequencies, suggesting that an improved model might be required to help to distinguish the correct α - F_2 crystal structure. Solid fluorine more closely resembled solid oxygen than it did the other solid halogens. In particular, the intermolecular forces were extremely weak, as exemplified by the small shifts of the internal frequencies from their gas phase values, the absence of observ-

able factor group splitting of the fundamental and the overtone, and the relatively low values of the external (lattice) frequencies.

2.13.1.3 Raman Fluorescence Spectra of Fluorine

The rotational constants of the F_2 molecule in the electronic ground state were determined from the rotational and vibrational Raman spectra of gaseous fluorine at 1 atm [198]:

$$\begin{aligned} B_0 &= 0.8828 \text{ cm}^{-1} \\ r_0 &= 1.4177 \pm 0.001 \text{ \AA} \\ \Delta G_{1/2} &= 891.85 \pm 0.4 \text{ cm}^{-1} \end{aligned}$$

The intensity alternation in the rotational spectrum showed that the nuclear spin of fluorine was $1/2\hbar/2\pi$ and that the ^{19}F nuclei followed Fermi statistics.

The depolarization factors in Raman spectra of gaseous fluorine were measured with laser excitation [199]. The optical systems were able to produce a laser beam free of unwanted emission lines and focus scattered light on the slit and on the detector. The rotational spectrum of gaseous F_2 has been used as an example to determine a rotational constant of $B_0 = 0.8841 \pm 0.0006 \text{ cm}^{-1}$, corresponding to $r_0 = 1.4168 \pm 0.0005 \text{ \AA}$.

A band shape study of the Raman diffusion by liquid fluorine over the temperature range 75–100 K offered an explanation of the molecular reorientation process [200, 201].

The pure rotational Raman spectrum of $^{19}\text{F}_2$ has been recorded photographically with a reciprocal linear dispersion of $1.4 \text{ cm}^{-1} \text{ mm}^{-1}$ and analyzed to yield: $B_0 = 0.88331 \pm 0.00004 \text{ cm}^{-1}$; 10^6 , $D_0 = 3.48 \pm 0.06 \text{ cm}^{-1}$; $r_0 = 1.41744 \pm 0.00006 \text{ \AA}$ [202]. Assuming from earlier work, $B_1 = 0.872 \pm 0.002 \text{ cm}^{-1}$, the following equilibrium constants were obtained: $B_e = 0.889 \pm 0.001 \text{ cm}^{-1}$; $r_e = 1.4131 \pm 0.0008 \text{ \AA}$. These were the most precise values reported for B_0, D_0, r_0, r_e of $^{19}\text{F}_2$ up to that time. The experimentally determined D_0 value was in good agreement with the value calculated from B_0 and ω_0 .

The Raman spectra and phase diagram of fluorine were studied in a diamond-anvil cell at extremely high pressures up to 6 GPa over the temperature range 10–300 K [203]. The sample slowly reacted with the diamond anvils to form CF_4 . The vibron frequencies in $\alpha\text{-F}_2$ and $\beta\text{-F}_2$, as well as the lattice modes in $\alpha\text{-F}_2$, were determined as a function of pressure. No new phases were discovered at the high pressure. The $\alpha\text{-}\beta$ phase boundary could be fit with an equation of the Simon form:

$$P \text{ } \alpha\beta \text{ (GPa)} = -0.385 + 4.80 \times 10^{-4} T_{\alpha\beta}^{1.75} \text{ (K)}.$$

The melting curve was established to lie between limiting curves:

$$P \text{ upper melt (GPa)} = -0.107 + 1.01 \times 10^{-4} T^{1.75} \text{ melt (K)}$$

and

$$P \text{ lower melt (GPa)} = -0.140 + 1.32 \times 10^{-4} T^{1.75} \text{ melt (K)}.$$

2.13.1.4 Photoelectron and X-ray Photoelectron Spectra of Fluorine

Threshold photoelectron spectra and photoionization thresholds of HF, DF, and F₂ were investigated using a simple threshold photoelectron energy selector in the source of a conventional photoionization mass spectrometer [204]. A number of vibronic levels of the HF⁺ and DF⁺ ions, not previously observed by HeI photoelectron spectroscopy, have been detected, from which spectroscopic constants of the molecular ions could be inferred for comparison with recent emission spectroscopy data. The threshold photoelectron spectra showed some complicated structure associated with resonant autoionization of molecular Rydberg states belonging to series converging to the various vibronic levels of the ions.

Diatomic halogens including difluorine were studied with UV photoelectron spectroscopy using new techniques to preserve high resolution even for reactive species [205]. Vibrational structure was observed on the ²Π_{u,i} (*i* = 1/2, 3/2) states of F₂⁺ and Cl₂⁺ and the ²Σ_g⁺ states of F₂⁺ and Cl₂⁺. On the ²Π_{u,i} states (F₂⁺, Cl₂⁺, Br₂⁺) spin-orbit splitting was resolved. Indications for a small potential barrier on the F₂⁺(²Π_{u,i}) state for large internuclear distances were found. The complementary nature of optical emission and photoelectron spectroscopy for small ions was demonstrated, leading to a more complete picture of the F₂⁺(²Π_{u,i}) and Cl₂⁺(²Π_{u,i}) ionic states.

2.13.2 Index of Refraction of Liquid Fluorine

The refractive index (“index of refraction”) of liquid and gaseous fluorine is summarized in Table 30.

Table 30: Refractive index of fluorine.

Physical state	Temperature, K	Refractive index	Wavelength, nm
Liquid fluorine	at normal boiling point	1.20	Na _D
Gaseous fluorine	273	1.000214	589
For comparison:			
Gaseous oxygen	273	1.000403	589
Gaseous nitrogen	273	1.000298	589
Gaseous hydrogen	273	1.000139	589

Data source: [206]

Elementary fluorine possesses the lowest polarizability after He, Ne, and H₂. This indicates a very dense packing of electrons in the shell. These data can also be used to calculate the dielectric constant of liquid fluorine.

2.13.3 Dielectric Constant of Liquid Fluorine

The dielectric constant ϵ can be calculated from the ratio of the capacitance of a filled capacitor cell to that of an evacuated cell. The dielectric constants and molar polarizability of saturated liquid fluorine and compressed liquid fluorine were measured at the NBS in a capacitance cell at 5 kHz and temperatures ranging from the triple point (53.48 K) to the critical point (144.31 K) and pressures up to 21 MN/m² (3045 psia) [207]. Dielectric constant ϵ and molar polarizability P are connected through the Clausius–Mossotti equation where

$$P = [(\epsilon - 1)/(\epsilon + 2)] \times \rho^{-1}$$

is nearly independent of density ρ . The molar polarizability is found to increase initially with density and then decrease. Current theories of the dielectric constant are thought to give satisfactory qualitative interpretation of the density dependence of the molar polarizability, but lack quantitative accuracy. Measurement of the molar polarizability offers a convenient method for determining the density of propellants in the laboratory as well as in the tanks of flight vehicles. The dielectric constant drops off very steeply as the temperature approaches the critical point (Table 31 and Figure 15).

Table 31: Dielectric constant of saturated liquid fluorine.

Temperature			Dielectric constant	Molar polarizability cm ³ /mol
K	°C	°F		
53.48	-219.62	-363	1.4913	3.1363
70	-203	-333	1.4577	3.1385
80	-193	-315	1.4362	3.1389
90	-183	-297	1.4136	3.1397
100	-173	-279	1.3895	3.1408
110	-163	-261	1.3631	3.1423
120	-153	-243	1.333	3.1442
130	-143	-225	1.2959	3.1461
140	-133	-207	1.2398	3.1473
141	-132	-206	1.2311	3.148
142	-131	-204	1.2208	3.1484
143	-130	-202	1.2073	3.15
144.31	-128.84	-200	1.1498	3.1500 (extrapolated)

Data source: [207]

Figure 15: Dielectric constant of saturated liquid fluorine. (Reprinted and modified from [207], with the permission of © 1972 AIP Publishing; permission conveyed through RightsLink.)

The data are lower, but much more accurate than those reported earlier by [170]. The data by Kanda were eliminated from the current book.

The molecular polarizability of liquid fluorine is $1.242 \pm 0.001 \text{ \AA}^3$. The dielectric constant of liquid fluorine at its normal boiling point was calculated from gaseous fluorine refractive index data as $\epsilon = 1.43$, compared with $\epsilon = 1.48$ for liquid oxygen or $\epsilon = 1.45$ for liquid nitrogen [206].

2.13.4 Magnetic Properties of Liquid Fluorine

2.13.4.1 NMR Spectra of Fluorine

Direct comparisons between ^{19}F nuclear magnetic resonance (NMR) spectra of liquid and gaseous F_2 , OF_2 , and NF_3 had not been reported prior to 1966 [208]. Previous publications listed the chemical shift of F_2 gas as -414 ppm (in relation to CFCl_3) and -422 ppm (in relation to SF_6). The chemical shifts of liquid and gaseous F_2 , OF_2 , and NF_3 are listed in Table 32.

Table 32: ^{19}F NMR shifts in liquid and gaseous F_2 , OF_2 , and NF_3 .

	^{19}F NMR Shifts ^a		
	F_2 (ppm)	OF_2 (ppm)	NF_3 (ppm)
Liquid at 77 K	-422 ± 1	-249 ± 1	-142 ± 1
Gas	-419 ± 1	-248 ± 1	-138 ± 1
Difference gas – liquid	3	1	4

^a CFCl_3 reference.

Data source: [208]

As can be seen in Table 32, the chemical shifts for liquid F_2 , OF_2 , and NF_3 were all lower than the corresponding shifts in the gas. This downfield shift due to liquefaction is similar to that observed in the proton magnetic resonance studies of the first-row hydrides.

3 Chemical Properties of Fluorine

Fluorine is a pale yellow, corrosive gas, which reacts vigorously with many organic and inorganic substances. Otherwise inert materials, such as finely divided metals, glass, carbon, and even water, can burn in fluorine with a bright flame. This reactivity makes the selection of materials of construction a very difficult task. The free element has a characteristic pungent odor, detectable in concentrations as low as 20 ppb, which is below the safe working level. The recommended maximum allowable concentration for a daily 8-ho time-weighted exposure is 1 ppm (see Section 8 on the toxicity of fluorine).

The family of fluorine (fluoride) compounds can be categorized by the type of bond. Most fluorides have an ionic bond, whereas all fluoroorganic compounds have covalent C–F bonds. Non-metallic fluorine compounds have transitions between strongly polarized and covalent bonds.

Fluorine is the most reactive of all elements. There are only a few compounds or elements it does not react with. Even with some of the so-called noble gases it forms fluoride compounds, challenging the nobility of these elements. Reactions with sulfur, phosphorus, or selenium start at cryogenic temperatures, whereas oxygen and nitrogen cannot be made to react with fluorine at room temperature and it requires activation by UV irradiation or a glow discharge.

For the production of compounds such as oxygen difluoride OF_2 and nitrogen trifluoride NF_3 , methods are required other than direct synthesis from the elements. Alkali and alkaline earth metals (except magnesium) ignite in fluorine spontaneously and combust with the formation of saline metal fluorides. Fortunately, many metals, in particular those intended as materials of construction for fluorine apparatus, are

protected from further attack by formation of a protective coating of metal fluorides. This is called a passivation film. Inadvertent scratches in the passivating layer or flaking of the protective coating on bending of the metal may be the points of initiation of renewed, sometimes catastrophic reactions of fluorine with the metal. Corrosion by fluorine and recommended methods of passivation and corrosion prevention are discussed in more detail in Section 4.1.

Non-graphitized carbon (activated charcoal), which reacts with chlorine only at elevated temperatures, reacts with fluorine at room temperature in a spectacular display of sparks with a bright flame. This reaction, when conducted in a controlled manner, can be used for the disposal of excess fluorine. Most hydrogen-containing compounds react with fluorine spontaneously and ignite hypergolically, a desirable property for rocket propellant applications. This reactivity is often explained by pointing to the high enthalpy of formation of HF and the high affinity of fluorine to hydrogen. The hydrogen abstraction from hydrocarbons or hydronitrogens is one of the fastest reactions. Other text books try to explain the hypergolicity of difluorine with hydrogen compounds by stating that difluorine readily dissociates into atomic fluorine and that fluorine atoms as free radicals start chain reactions. Even at room temperature there are sufficient free radicals of atomic fluorine in a mixture with fluorine gas to start a chain reaction. Most covalent single bonds of fluorine with other elements are very strong bonds compared with the F–F bond in F₂. The low molecular mass and the high rate of diffusion of difluorine contribute to high global reaction rates. Only few fluorine reactions are kinetically or diffusion limited. Chlorine fluorides such as ClF and ClF₃ are also very reactive with most hydrogen compounds, some even more so than F₂ itself.

Summaries on fluorine chemistry and fluorine compounds such as those listed in Tables 1 and 3, including Haszeldine and Sharpe [42], Simons [43], Slessor and Schram [44], provide additional information, and on the history of fluorine chemistry [41, 209].

3.1 Reactions of Fluorine

Fluorine is one of the most reactive chemicals in the inventory and it reacts with just about everything except element fluorides in their highest state of oxidation. The reactivity of fluorine makes it difficult to find materials of construction that are compatible with fluorine in the liquid and/or the gaseous state. Accidental ignition of materials in fluorine has been the cause of many accidents. Most of the experience in reactions and handling of fluorine was gained in the nuclear industry, where uranium hexafluoride is used for isotope separation, and not in the aerospace industry. Additional experience was gained when fluorine was used in chemical lasers.

Instead of writing a chapter on all the chemicals that react with fluorine, it would be easier to write on the few chemicals that don't react with fluorine.

3.1.1 Reactions of Fluorine with Elements

3.1.1.1 Reactions of Fluorine with Hydrogen

A later set in this series, *Hypergolic Combinations*, will contain a detailed discussion of the reactions of fluorine with hydrogen and deuterium as they are applied to rocket propulsion and chemical lasers.

Apparently early on in the development of fluorine chemistry there was a dispute about the interpretation of reactions of liquid hydrogen with solid fluorine as interpreted by Dewar, Eyring, and eventually, Aoyama and Kanda, and the experiments were repeated with different results [210]. An attempt was made to solve the disagreement between the results of Moissan and Dewar [211], who reported the occurrence of an explosion when a test tube with solid fluorine was immersed in liquid hydrogen and fractured, and the results reported by Wartenberg and Taylor [212] or Eyring and Kassel [213] who failed to reproduce this reaction. With a 10-mm glass tube containing 1 mL of liquid fluorine, a slight explosion occurred, and flames appeared on the surface of the hydrogen. It was suspected that sunlight might initiate the reaction, but that was not confirmed by performing the test under a mercury UV lamp. The results are not in line with earlier suggestions that any explosion results from the presence of organic matter, e. g., rubber. A mixture of the two gases hydrogen and fluorine failed to explode at ordinary temperature either in sunlight or under the influence of a Hg lamp.

3.1.1.2 Reactions of Fluorine with Boron

Once ignited, boron burns in fluorine with a bright green flame, forming boron trifluoride, a gaseous combustion product. Thus, it does not have the same handicap with condensable exhaust species as aluminum combustion in oxygen.

Fluorine/boron combustion experiments were carried out with both single-crystal and polycrystalline boron rods to determine the regression rate of the boron surface. For single-crystal boron fluorination in the 0.1 to 1 mm Hg region, the data indicated a reaction that was independent of fluorine pressure up to about 600 K. At around this temperature there was a change in the rate-limiting process and the rate increased with fluorine pressure [214–216]. Such combinations could be used in a hybrid rocket engine. Rocket propellant performance calculations of fluorine/boron and fluorine/boron hydrides will be presented in future sets of the *Encyclopedia of Rocket Propellants*.

3.1.1.3 Reactions of Fluorine with Aluminum

Once ignited, aluminum burns in fluorine with a bright white flame, forming aluminum trifluoride.

Aluminum particle combustion in fluorine-containing atmospheres is significantly different from aluminum particle oxidation in air or oxygen. The most notable difference between the Al-O and Al-F systems is that the analog to slag-forming

liquid $\text{Al}_2\text{O}_3(\text{L})$, liquid aluminum trifluoride $\text{AlF}_3(\text{L})$, does not exist. AlF_3 is the principal product species of the Al-F system. AlF_3 is solid at room temperature and sublimates to gaseous AlF_3 and its dimer, Al_2F_6 , at 1550K. The heats of formation of $\text{AlF}_3(\text{S})$ and $\text{AlF}_3(\text{G})$ are -361 and -298 kJ/mol respectively. Because most of the heat of combustion is evolved directly by the formation of gaseous AlF_3 , the flame temperature is not limited by the sublimation characteristics of AlF_3 . Owing to the absence of any condensed-phases at temperatures above 1550 K, aluminum particle combustion in fluorine would be similar to fuel droplet combustion. Aluminum particle combustion was studied in SF_6 and mixtures of SF_6/O_2 and SF_6/Ar [217]. Although SF_6 is used more often as a torpedo propellant than as a rocket propellant, some of the metal/fluorine interactions can be studied with this less corrosive and less toxic fluoride.

See also Section 4.1.9 on passivation of aluminum metal in gaseous fluorine.

3.1.2 Reactions of Fluorine with Inorganic Compounds

Fluorine bomb calorimetry has developed as a mature technology to determine the heats of formation of a wide range of inorganic and organic compounds [218]. The ultimate products of such calorimeter reactions are HF and CF_4 , besides N_2 and O_2 .

3.1.2.1 Reactions of Fluorine with Water

In looking for chemicals that are in abundant supply and that can be used to destroy and neutralize excess fluorine, the first choice would be water. However, fluorine does not react with water at room temperature. The reaction with water starts only at elevated temperatures and is often inhibited [219]. Once started, the reaction can proceed explosively [220–222]. The reaction of fluorine with water

is highly exothermic. When combining the reactants at 308 K (35°C) and 5.3 kPa (40 mm Hg), the gas phase reaction is very slow and its progress is barely measurable [223]. Studies of diffusion flames and premixed flames of fluorine with hot water vapor (steam) showed that the ignition boundaries of the mixture are at 19 and 95 mol-% F_2 (at an initial temperature of 373 K = 100°C and sea-level atmospheric pressure of 1 atm) [224]. Pure fluorine and steam can be premixed at atmospheric pressure without ignition. The mixture did not autoignite under these conditions, but once ignited, a flame would be sustained in the upward direction. The maximum flame speed was 810 ± 10 cm/s and was obtained with a mixture containing 47.5 mol-% fluorine and 52.5 mol-% steam (Figure 16).

Similar flames are formed with oxygen difluoride and steam [225].

If the electrolyte from which fluorine is made by electrolysis is not kept meticulously dry and free of water, some of the fluorine will evolve as OF_2 instead of F_2 .

3.1.2.2 Reactions of Fluorine with Tetrafluorohydrazine

The rate of the exothermic free radical reaction

has been directly determined by measuring the disappearance of fluorine and the initial rate of NF_3 formation in the temperature range 1100 to 1600 K by means of a shock tube coupled with a TOF mass spectrometer [226]. The Arrhenius expression

$$k_a = 4.8 \times 10^9 \exp(-14400/RT) \frac{\text{mol}}{\text{s}}$$

was obtained for the rate constant, which, when extrapolated ($\sim 10^7$) to near room temperature, is in reasonable agreement with corrected data. The dissociation of fluorine in neon was also studied in the temperature range 1400 to 2000 K where $k_{\text{F}_2} = 2.0 \times 10^{10} \exp(-35000/RT) \text{ mol/s}$ was an Arrhenius fit to the data.

Fluorine reacts with most other compounds spontaneously at room temperature and those that don't, sometimes need a little help in the form of an electric discharge or UV illumination or high temperature and high pressure. In some cases this may lead to compounds in higher states of oxidation, but in the case of NF_3 it did not work for the synthesis of NF_5 , which would be a desirable rocket propellant if it could be made and stabilized [227].

3.1.2.3 Reactions of Fluorine with Carbon Monoxide and Carbon Dioxide

The reaction between carbon dioxide and fluorine at 303–523 K under various pressure and mixture ratios of both gases forms mixtures of CF_3OF , COF_2 , CF_4 , and $\text{CF}_2(\text{OF})_2$ [228]. The best yield of COF_2 was 11.1% under the reaction condition of $\text{CO}_2/\text{F}_2 = 76 \text{ kPa}/76 \text{ kPa}$ at 498 K for 72 h in a direct reaction.

Attempts to obtain a clean stream of COF_2 by direct fluorination of carbon monoxide with elemental fluorine or by electrochemical fluorination were wrought with problems because the reaction is highly exothermic, difficult to control, and can easily develop into a thermal runaway situation [229]. Under fuel-rich conditions the main product is COF_2 , together with the unreacted carbon monoxide but an excess of fluorine, leads to perfluoro-methyl-hypofluorite (CF_3OF) along with the main product. Performing the reaction in a stainless steel parallel channel microreactor succeeded in controlling the exothermic reaction. Under the same experimental conditions a full-scale reactor suffered serious corrosion that led to nozzle meltdown, lack of selectivity, and frequent plant shutdowns.

3.1.3 Reactions of Fluorine with Organic Compounds

Under uncontrolled conditions, most reactions of fluorine with organic compounds will cause bursting into flames and the final products are tetrafluoromethane and HF. Under carefully controlled conditions, usually working with highly diluted fluorine or at low temperatures, it is possible to fluorinate organic compounds selectively and thus make them more resistant to environmental effects.

Of all the single bonds formed by carbon, the strongest is the one with fluorine, which therefore occupies a special place as a substituent in organic chemistry. Despite this, knowledge of organic fluorine compounds accumulated more slowly in the early years after fluorine discovery than inorganic reactions.

Numerous pharmaceutical medicines carry one or several fluorine atoms in specific locations, thus enhancing their selectivity and healing activity. It has been estimated that 20% of all pharmaceutical drugs and 30% of all agrichemical products on the market contain fluorine. If elemental fluorine was used, the number of fluorine atoms added and their locations would be hard to control. Selective fluorinations are now possible with nucleophilic reagents used to form C–F bonds [230]. These

selective fluorination agents include diethylaminosulfur trifluoride, 2,2-difluoro-1,3-dimethylimidazolidine, *N*-fluorobenzenesulfonimide, and bis(2-methoxyethyl) aminosulfur trifluoride. These reagents transform alcohols into monofluorides and carbonyls into *gem*-difluorides. This is an example where military, nuclear, and space technology of fluorine chemistry has resulted in peaceful benefits to humankind at large by allowing the synthesis of more effective medicines [231].

Fluorine gas will react even with perfluorinated organic C_{>2} compounds, leading ultimately to CF₄ as the only stable end product. Attempts to extinguish fluorine-supported fires with a halocarbon-13B or -114B2 fire extinguishant such as those used on electronic equipment and high-value museum pieces would be futile.

Accidental ignition can occur in refrigeration equipment if the leaking refrigerant comes into contact with leaking fluorine. Interactions of coolants CFC-114, cyclo-C₄F₈, or C₄F₁₀ and fluorinating agents such as F₂ or ClF₃ were studied in an effort to determine if a particular mixture can sustain and propagate a flame if ignited, and what the maximum pressure generated by the burning (and possibly exploding) gas mixture might be [232]. Experimental data on such systems are limited, and therefore it was attempted to predict potential detonation pressures and the composition limits of flammability for these systems.

3.2 Pyrolysis of Fluorine

The rate of dissociation of molecular fluorine has been determined in the presence of argon in the temperature range 1300–1600 K by spectrophotometrically observing the disappearance of molecular fluorine behind shock waves in a shock tube [233]. Dissociation rate constants for the reaction

were determined in 5, 10, and 20% F₂ in Ar mixtures. In the 5% mixtures the result may be summarized by

$$\log k_D = 9.85 - \frac{6520}{T}$$

where $\log k_D$ is the rate constant in L mol⁻¹ s⁻¹ and T is the temperature in kelvin, which corresponds to an apparent activation energy of 30 ± 4 kcal/mol. The recombination rate constant calculated from the above value is only about one-tenth as large as the corresponding constant for I₂, Br₂, Cl₂, and H₂, all of which are roughly equal. Fluorine may be somewhat more effective than argon as a third body.

3.3 Photolysis of Fluorine

The reactivity of difluorine is often ascribed to the measurable percentage of fluorine atoms already present at room temperature. Although some reactions of difluorine, such as the reaction with dihydrogen, are inhibited at room temperature, they may get initiated by a flash of short-wavelength light from a flash bulb or a spark discharge [234]. Such initiators are required to get the reactions in a chemical F_2/H_2 or F_2/D_2 laser started. The absorption spectra and the light-induced dissociation are of interest for the participation of F_2 in chemical lasers.

The photolysis of fluorine has been investigated extensively because the photolysis of fluorocarbons in the upper atmosphere is contributing to destruction of the ozone layer. The recombination of fluorine atoms is one of the sinks for fluorine atoms. The reversal of that recombination is the photolysis (photodissociation) of difluorine. The photolysis reaction is also of interest for the reaction kinetics of chemical lasers with fluorine as the oxidizer.

The fluorine photodissociation dynamics in the first absorption band was completely characterized by detection of atomic fluorine using resonantly enhanced multi-photon ionization [235]. Jet-cooled parent molecules were excited into the repulsive $A^1\Pi_u$ state by a $3\sigma_u \leftarrow 1\pi_g$ electronic transition at 234 nm. Different intermediate excited states of atomic fluorine were observed between 126500 and 128500 cm^{-1} in a (3+1) ionization process.

Ultraviolet illumination of mixtures of fluorine with other elements (O_2 , N_2) or compounds (ClF_3) is one method of getting reactions started. The first step in these photochemical reactions is the photodissociation of difluorine, forming fluorine atoms. This is usually done with short wavelength light, but it can also be done in the visible and red spectral range. A search has been made for new, low-energy pathways of the reaction

through excitation of F_2 or O_2 in an oxygen matrix with red and near infrared photons [236]. By monitoring the product yield as a function of laser irradiation frequency, a reaction excitation spectrum of $O_2 + F_2$, which began at 14500 cm^{-1} , was recorded, and extended through the entire red spectral range. It revealed two discrete absorptions $O_2^1\Sigma_g^+, \nu' = 1 \leftarrow {}^3\Sigma_g^-, \nu'' = 0$ and $(O_2)_2(^1\Delta_g, ^1\Delta_g)0,0 \leftarrow ({}^3\Sigma_g^-, {}^3\Sigma_g^-)0,0$, and a continuous, oxygen-enhanced absorption of F_2 , which was assigned to excitation to the repulsive part of the weakly bound ${}^3\Pi_0^+{}_u$ state. The F_2 absorption detected in this experiment extended more than 200 nm to longer wavelengths than any electronic absorption of molecular fluorine reported so far.

3.4 Analysis of Fluorine

In order to determine the assay of a sample of liquid fluorine, the sample has to be evaporated first and the gas can then be analyzed by several methods. If there is a non-volatile residue (most likely consisting of corrosion products), it has to be analyzed separately.

The purity of fluorine that was procured as a rocket propellant for the US Air Force (USAF) was defined by Military Specification MIL-P-27405, which was only circulated as a draft and apparently never formally issued [237]. The proposed F_2 assay was 99 vol.-% min. The maximum allowed sum of CO_2 and CF_4 was 0.2 vol.-% as determined by IR spectrophotometry and the maximum allowed sum of $O_2 + H_2$ was 0.8 vol.-% as determined by gas chromatography. The nuclear industry may have had a different specification.

Additional information on the analysis of fluorine, HF and other fluorine compounds is summarized in [238–240].

A program was undertaken to develop, evaluate, and deliver a liquid fluorine sampler as a part of a coordinated effort to develop the component technology and ground support equipment required to meet potential requirements for high-energy rocket propulsion systems [241]. The program demonstrated the capability to take liquid fluorine samples, separate particulate from the fluorine sample, using a filter integral with the liquid fluorine sample chamber and provided both volatile and non-volatile particulate samples.

3.4.1 Volumetric Methods for the Analysis of Fluorine

A traditional method for analysis of fluorine mixtures with other gases is to pass the sample over a bed of alkali metal halogenide (other than fluoride) powder to liberate a stoichiometric amount of the other halogen which can then be determined by conventional wet chemistry titrimetric methods [60]:

or

The older halogen conversion analysis method by [60] was quite complicated and time-consuming. It was based upon the reaction of HF with sodium fluoride, the conversion of fluorine to chlorine by reaction with sodium chloride, and analysis of the chlorine for oxygen and inert gases by standard methods. The over-all error in fluorine purity by this method was supposed to be less than 0.4%.

A faster method may be the gasometric assay of fluorine by reaction with mercury. There are two mercury methods in the literature, one with boiling mercury [242] and one operating at room temperature [243] and [244]. The apparatus for the latter method

consists of a 500-mL three-necked round-bottom glass flask with a separatory funnel containing mercury, a glass-covered magnetic stirring bar and a stirring motor with a magnetic coupling. The flask is connected to a sampling train which also carries a U-gauge separated by a shut-off valve, a fluorine inlet valve, an oxygen (or air) inlet valve and a NaCl tube to destroy (convert) excess fluorine. The apparatus must be passivated with dry fluorine gas for at least 16 h prior to its first use. It is difficult to find an inert fluid for the U-gauge manometer. One might use mercury protected by a layer of perfluorinated oil, but it is difficult to keep a clean mercury meniscus. The internal volume of the system must be known very accurately prior to the test. At the beginning of the analysis, one admits fluorine to the apparatus, equilibrates the pressure, shuts of the vent valve, admits 10 mL of mercury to the flask and begins stirring. The stirring is continued until the freshly formed mercury surface remains shiny and the formation of mercury fluoride ceases. The remaining non-reactive gas is admitted to an evacuated manometer system and the residual pressure is determined. The method has also been used for the analysis of oxygen/fluorine mixtures. Oxygen does not react with mercury under the conditions of this test. One can also use a smaller apparatus [169].

3.4.2 Gas-Chromatography Methods for the Analysis of Fluorine Compounds

Nowadays gas analysis can be performed faster and more accurately by gas chromatography. Of course all off-the-shelf GC equipment has to be modified to make it compatible with corrosive gases such as fluorine [245, 246] and other volatile fluorides [247].

Poly(trifluoromonoethylen) oils were used as stationary phases after chemical stabilization [248]. Plasticizing halogenated polymers with halogenated oils created useful stationary phases for column packing [249], and many of those gas chromatography methods involved the separation of reactants in uranium isotope separation plants with UF_6 [250]. In this method, one or several chemical “precolumns” were placed in series with a gas–liquid chromatography (GLC) column. The “precolumn” system retained or destroyed the corrosive compounds (UF_6 , HF, F_2) and the chromatography column separated the components formed.

Another method of analysis of fluorine/oxygen mixtures reacts the gas first with NaCl to form Cl_2 and then analyzes the gas mixture using GLC. It can also be used for the analysis of FLOX [251]. A similar instrument was described in [252]. The electrolysis of wet HF or wet $\text{KF} \cdot \text{HF}$ may produce some ozone as a contaminant in the gas. The ozone concentration in fluorine or oxygen difluoride can be measured by gas chromatography [68]. See also Million et al., [253, 254], Pappas and Million [255], and De Grazio and Auge [256].

The separating efficiency of column packings depends on the viscosity of the stationary phase and its affinity to the fluorides to be analyzed (F_2 , HF, UF_6) [257].

An in-line gas chromatograph made entirely of materials that are corrosion-resistant against fluorine and fluorides has been constructed using two different columns and an automatic sampling system [258]. The separation columns were optimized for a simulated process of gas composition containing N_2 , O_2 , F_2 , and UF_6 , in order to obtain complete peak separation. The column selected for UF_6 analysis was Cu tubing measuring 0.4 cm in diameter, tubing measuring 3 m long packed with 40% poly-trifluoromonochloroethylene oil on poly-tetrafluoroethylene powder. The column for F_2 analysis was a combination of this column with a conversion column packed with KCl powder. Under these conditions, the retention time was 9 and 3 min. for UF_6 and F_2 respectively at a carrier gas flow rate of 100 mL/min. The calibration curves were linear with a zero intercept, and the detection limits were 0.2 and 1 mm Hg in partial pressures of UF_6 and F_2 respectively with a 10-mL sampling volume.

The concentration of F_2 in gas mixtures such as those fed to excimer lasers can be determined by passing the mixed gas through a column packed with an alkali metal oxide or alkaline earth metal oxide, which has no halogens and reacts with F_2 to form a solid fluoride together with molecular O_2 and/or CO_2 and measuring the concentration of O_2 and/or CO_2 in the non-corrosive outflowing fluorine-free gas [259]. If the mixed gas contains molecular O_2 and/or CO_2 to start with, its concentration must be measured separately after fixing F_2 in another column packed with an element, which forms a fluoride. This analyzing method can be used in a feedback closed-loop control system for controlling the concentration of F_2 in the gas fed to an excimer laser during operation of the laser to stabilize the laser output power.

For continuous monitoring of the fluorine purity, a gas chromatographic method with series parallel connection of nine columns with two temperature-conditioned ovens was developed [260]. The corrosion problems have been solved. The fluorine purity and the concentrations of impurities in the fluorine gas can be measured accurately by this method.

Fluorine produced by electrolysis usually contains impurities such as nitrogen, HF, and carbon tetrafluoride. The carbon tetrafluoride content can be determined by GLC after replacing chlorine in sodium chloride using fluorine and absorbing the chlorine in aqueous NaOH solution [261].

3.4.3 Spectrophotometric and Colorimetric Methods for the Analysis of Fluorine Mixtures

Other methods for instantaneous analysis of gaseous fluorine/oxygen mixtures, such as those formed by evaporation of FLOX, are based on UV-spectrophotometric analysis of the gas mixture flowing through a Teflon[®]-coated flow-through absorption cell from stainless steel with CaF_2 windows. The instrument was light-weight and portable and was intended to be used right at the rocket test site. Prior to the first use, a calibration series had to be run with a series of gas mixtures with known fluorine content. This

instrument was developed by the Astronautics Division of the General Dynamics Corporation.

Another continuous spectrophotometric analysis instrument was based on the reaction of fluorine with sodium bromide at 503 K (230 °C) [262],

converting fluorine into a stoichiometric amount of bromine. The gases were then passed over a bed of NaF, which was intended to absorb HF, which otherwise would etch and opacify the windows of the spectrophotometer cell in which the bromine concentration was measured by light absorption at 435 nm. The accuracy in the range from 30 to 40 vol.-% fluorine was only $\pm 3\%$ relative. In the range from 0 to 30 vol.-% fluorine it was $\pm 1\%$ relative. A similar instrument that operated at 423 K (150 °C) measured the bromine concentration at 425 nm with an accuracy of 0.5% for fluorine contents from 0 to 10% [263].

Although fluorine can be recognized by its pungent odor at very low concentrations (~2 ppm), instrumented air surveillance is necessary at all rocket test sites using fluorine oxidizers in order to detect leaks at an early stage. In consideration of the toxicity, the fire hazard, and the corrosive damage caused by fluorine, it is necessary to analyze the air in and around rocket test sites during and after rocket engine tests for traces of fluorine and HF. Several instruments were developed specifically for this purpose. One was a modification of an existing pump colorimeter called Mini-Adak [264]. The reagent was the intensely colored complex of iron(III) with ferron, which becomes colorless in the presence of fluoride. Ferron is 8-hydroxy-7-iodo-quinoline-5-sulfonic acid. The full range of the instrument was 0.1 to 200 mg fluoride/m³. Similar instruments had been used for the analysis of HF in flue gas of aluminum smelters and phosphate fertilizer plants.

An automatic analyzer has been developed for the continuous determination of elemental fluorine in gas mixtures [265]. As the sample stream is passed through hot sodium chloride, the fluorine quantitatively liberates elemental chlorine according to

the light absorption of which was measured at 360 nm in a pressure-controlled flow colorimeter cell. Some chlorine was adsorbed by sodium chloride below 473 K (200 °C), introducing a response lag and some error. The range of the analyzer, calibrated with standard fluorine/nitrogen mixtures, was 0.05 to 15 mol.-% F₂, using a 10-cm cell at a pressure of 500 mm Hg. The relative standard deviation of the fluorine analyzer was about $\pm 1.5\%$ above 0.8% fluorine, and the standard deviation was about ± 0.04 (absolute) at lower levels. Initial response lag was 6 s, with full response in about 1 min. This method is applicable in the presence of HF and other gases that do not absorb radiation near 360 nm or liberate chlorine from sodium chloride.

A continuous fluorine–HF analyzer was developed that was designed to monitor fluorine gas mixtures containing between 0 and 50% F₂, the best accuracy being in the

range from 4 to 30% F₂ ($\pm 5\%$ relative) [266]. The length of time a given sample could be monitored was less than 5 min.

3.4.4 Gas Detection Tubes and Lapel Monitors for the Detection of Fluorine in Work Room Air

For quick spot checks for fluorine or HF in air one can use colorimetric gas test tubes, such as those offered by Draeger or MSA. The HF tube uses a zirconium–alizarin dye supported on silica gel granules that changes color in the presence of HF. The Draeger fluorine gas detection tubes are sensitive to as little as 0.1 ppm F₂ and can measure up to 2 ppm F₂ with ten strokes (Table 33).

Table 33: Draeger fluorine and hydrogen fluoride gas detection tubes.

Tube designation	Concentration range	Draeger part number
Fluorine 0.1/a	0.1–2 ppm	81 01 491
Hydrogen fluoride 0.5/a	0.5–90 ppm	81 03 251

Data source: <http://www.draeger.com/sites/assets/PublishingImages/Products/tubes-for-short-term-measurements/US/tubes-accuro-pump-pi-us.pdf>

It would be convenient to have lapel-mounted badges that immediately change color if exposed to hazardous fluorine concentrations. Similar badges and portable detectors were evaluated for other volatile fluoride rocket propellants [267].

3.4.5 Electrochemical Methods for the Analysis of Fluorine in Air

In order to analyze fluorine by electrochemical methods, it first has to be converted to fluoride by absorption in alkaline water. An electrochemical fluoride analysis method was developed based on the electrochemical potential of a cell:

In the presence of fluoride, the concentration of free aluminum ions decreased and the potential across the electrodes changed proportionally [268]. Other instruments were based on the same electrochemical principle.

A portable continuous analyzer for gaseous fluorides in industrial environments responded to all substances that formed fluoride ions in aqueous solution and was specific to fluoride in the presence of common air contaminants [269]. The range of the instrument was 0.1 to 10 mg of fluoride per liter of air, with a higher upper limit available through proper selection of air and solution flows.

The instruments can be miniaturized to fit in a shirt pocket as personnel monitors [270].

These instruments would probably respond to the presence of free elementary fluorine as well, but not in a reproducible manner. Instruments capable of analyzing free fluorine would take advantage of the strong oxidizing power of this element. Most of these would also respond to chlorine or ozone and may thus not be specific to fluorine. Monographs on air pollution contain detailed chapters on analysis of F_2 and HF in the air [271].

Measurements of fluorine dispersion in the atmosphere during a liquid fluorine spill test in a remote area were made using an electrochemical method initially developed for ozone measurement. In this instrument, air containing oxidant (O_3 or F_2) oxidizes the iodide ion in a buffered KI solution in a cell containing platinum and silver electrodes [272]. The iodine formed is reduced at the silver cathode. Insoluble AgI is produced on the cathode so that the iodide is removed from the reaction. This system was made specific to fluorine by substituting LiCl for the KI solution. Atmospheric pollutants do not affect the salt. Fluorine, however, oxidizes the chloride ion, which undergoes the following electrode reactions:

For every molecule of fluorine, two electrons flow through the coulometric circuit and two atoms of chlorine are transferred from solution to cathode. Hence, the current generated may be calculated to be $0.14 \mu A$ times the flow in $mL \min^{-1} ppm^{-1} F_2$ in the atmosphere. This current was easily measured when the flow rate was between 100 and 300 mL/min.

A HF/DF detector was developed to monitor the atmosphere in the vicinity of chemical laser testing to ensure that the scrubbers are working properly and warn adjacent facilities if combustion products or unburnt propellant should escape accidentally [273]. The system uses a continuous impinger and a fluoride ion-selective electrode. The apparatus is portable and it takes only 5 min to set it up in the field and calibrate it.

3.4.6 Other Methods for the Analysis of Fluorine in Air

A prototype detector for atmospheric fluorine and HF using radiochemical exchange of kryptonates was developed and evaluated [274, 275]. The instrument utilized silicon kryptonate for the detection of HF and hydroquinone clathrate for the detection of elemental fluorine. The instrument was capable of simultaneously detecting HF at concentrations of 0–50 ppm by volume and fluorine at 0–10 ppm by volume.

Microchemical methods have been developed for the determination of elemental fluorine in air [276]. A similar micro method was described for the determination of oxygen difluoride in air [277].

Regardless of how fluoride ion is analyzed once it has been captured from the air and is dissolved in water, the most important step in sampling air with an impinger is the completeness of absorption of the analyte in the liquid absorbent solution in the impinger. The efficiency of widely used sodium hydroxide as the impinger absorption solution for analysis of elemental fluorine in air was examined [278]. A recovery of 98% was obtained with a single scrubber in the concentration range 3–4480 ppb. Sodium hydroxide depletion by other acid waste gases from the air is not a factor as long as excess alkalinity is present. Gradual conversion of the NaOH to Na₂CO₃ during sampling periods due to absorption of atmospheric CO₂ did not significantly change the efficiency.

4 Materials of Construction for Fluorine

The selection of the proper materials of construction for fluorine service is a difficult task and must be done with the proper understanding of potential adverse reactions leading to ignition, explosions, leaks, or other failure modes. In addition to the references discussed in detail in this chapter, there are numerous summaries in the literature that may serve as a starting point in the study of this subject (Table 34 contains mostly references that are not discussed in the text). In looking at the dates of publications in this section on materials compatibility, one will notice that most of them date back to the 1950s and 1960s. That is because 1946–1970 is the period when most of the early fluorine materials compatibility work was done, and very little more was done in the interim. Some of the work was already done during the secret Manhattan project during WW-II but was released only after the war.

Table 34: Materials compatibility with fluorine literature summary.

Author(s)	Topic(s)	Date	Pages	References
Brown	Resistance of materials	1946		[279]
Schmidt	Compatibility of metals	1958	16	[280]
Evans	Tankage materials	1960	18	[281]
Schmidt and Rothenberg	Using fluorine in rocket systems	1960	19	[282]
Kleinberg and Tompkins	Compatibility of metals	1962	157	[66]
Cabaniss and Williamson	Corrosion of metal alloys	1963	31	[283]
Cabaniss	Bibliography	1964	84	[9]
Defense Metals Information Center	Compatibility of materials with fluorine	1965		[284]
Schmidt and Harper	Handling and use of fluorine	1967	279	[285]
Anderson	Dynamic compatibility of fluorine with metals	1972	75	[286]

A very thorough collection of literature references on fluorine and fluorine oxygen oxidizers for space applications is Cabaniss [9], with 353 references sorted by subject: materials compatibility, handling, storage, disposal, and safety considerations, physical and chemical properties, propellant oxidizer studies, and vehicle component design studies.

4.1 Metallic Materials of Construction for Fluorine

This section on the compatibility of metallic materials of construction with fluorine is subdivided such that publications dealing with more than one metal, more general overviews, are discussed first. The last several sections deal with specific metals, one at a time.

4.1.1 Metallic Materials of Construction for Fluorine; Multi-Metal Studies and Summaries

A very useful source of materials compatibility information are the Deutsche Gesellschaft für chemisches Apparatewesen (DECHEMA)-Werkstofftabellen [287]. The German-language compendium of corrosion data started as a basic loose-leaf collection in 1953 and since then has been continuously expanded by supplements, which are updated periodically. It describes the corrosion and chemical resistance of all technically important metallic, non-metallic inorganic and organic materials in contact with aggressive media. Parts of the DECHEMA-Werkstofftabellen have been translated into English and published in 13 volumes (second completely revised edition) as the DECHEMA Corrosion Handbook [288].

It is remarkable and difficult to explain that liquid fluorine at the temperature of liquid nitrogen may cause a worse corrosive attack of materials of construction than gaseous fluorine at room temperature. The only materials that are truly resistant to fluoride attack are the fluorides in their highest state of oxidation, but these are mostly brittle, crystalline materials and not useful for any structural load-bearing task.

Under the conditions of slow passivation of new fluorine systems, metals will be coated with a thin protective film of insoluble metal fluorides, which will protect the metal surface from further attack as long as the often brittle protective film is not compromised by scratching or bending. The maximum tolerable operating temperature of a given metal depends on the melting or sublimation point of the protective metal fluoride film. Table 35 gives a summary of melting and sublimation points of some of the fluorides that may form on the surface of metals.

Table 35: Melting and sublimation points of inorganic fluorides.

Below 294 K (21 °C)	294 to 589 K (21 to 316 °C)	589 to 1089 K (316 to 816 °C)	above 1089 K (816 °C)	References

Data source: extracted in part from [292], p. 62

Based on this temperature information one can make a preliminary selection of metals that are potentially useful for fluorine service because the fluoride coating has a high melting point and low volatility. All metals that form volatile fluorides cannot be allowed in alloys for fluorine service, not even at very low concentrations. That applies especially to carbon and silicon, which are common contaminants in steel.

The rate of corrosion of metals and other materials of construction by difluorine depends much on the presence of two contaminants that are sometimes hard to avoid: HF and water. Although carefully dried fluorine does not attack glass, traces of HF or moisture cause glass to lose its transparency in a very short time.

4.1.2 Exposure of Metals to Gaseous Fluorine

The exposure of metals to fluorine has been studied both in an academic setting to better understand the formation of passivating films, as well as in many fluorine conveyance and storage systems as part of developing passivating procedures that would prevent accidental ignition once the metal was exposed to fluorine for the first time. The fluoride film on metals forms during the first few minutes of exposure and the rate of film formation drops sharply after that time. Passivation procedures are discussed in Section 7 under handling precautions.

A study of the rates of corrosion of various metals in gaseous fluorine included stainless steels, iron, copper, aluminum, magnesium, nickel, titanium, and their alloys [292]. Other metals covered were Zr, Ta, Cr, Ag, U, Pt, and Sn. Depending on the particle size and condition of the surface, some of these metals may even autoignite at room temperature in gaseous fluorine.

Kinetic rate studies of this kind are useful for the development and selection of fluorine-resistant materials of construction. The rate of corrosion of 26 different metal

samples in gaseous fluorine was measured [293]. It was noticed that Si-containing Fe alloys are particularly susceptible to fluorine attack in the form of pitting corrosion. Once the samples ignited accidentally in fluorine, the reaction propagated with the intensity of a welding torch as long as the flow of fluorine was maintained.

A summary of the fluorine corrosion literature through 1956 contains data on Ni, Cu, Fe, Al, Mg, and their alloys, supported by numerous references, and is a good starting point for materials compatibility studies [294]. Sparse data are available on the behavior of non-metallic materials (carbon, graphite, asbestos, glass, quartz, ceramics, organic polymers) in fluorine.

As already indicated by the data in Table 35, nickel is very suitable as material of construction for fluorine service at higher temperatures. Table 36 gives additional data on the rate of corrosion of various metals in fluorine gas.

The reactivity of uranium, thorium, aluminum, copper, iron, magnesium, zirconium, and fluorothene [poly(1-chloro-1,2,2-trifluoroethene)] with bromine trifluoride, bromine pentafluoride, chlorine trifluoride, and fluorine was investigated at temperatures ranging from 298 to 683 K (25 to 410 °C) [290, 296].

A study of the corrosion of various metallic and ceramic materials by gaseous fluorine at elevated temperatures (673–1023 K = 400–750 °C) has been made to aid in the selection of materials of construction for the *Fluoride Volatility Process* applied to processing of irradiated plutonium–uranium alloys [297]. The data indicated that nickel and Monel were suitable materials for use in a fluorine atmosphere at temperatures up to 823 K = 550 °C. At higher temperatures, nickel and copper exhibited the lowest corrosion rates. Ceramic materials such as calcium fluoride and alumina were resistant to attack by fluorine even at the highest temperatures, but lack mechanical strength. This report also contains a very good summary of metal corrosion by fluorine gas data gathered from other literature sources.

The physical and chemical adsorption of fluorine on metals was studied using TGA, radioactive tracers, calorimetry, and IR spectrometry [298].

The extent of corrosion by fluorine at low pressure on several cryopanel materials was evaluated for conditions approximating those that might be expected in a space simulation chamber during rocket engine tests with fluorine-containing oxidizers [299]. The chamber pressure was adjusted to 530 Pa (4 mm Hg) of fluorine at room temperature and specimen temperatures were cycled between ambient and 77 K. The chamber was periodically pumped to high vacuums. The total exposure time exceeded 1000 h. CRES 304L, phosphorus-deoxidized copper, and Al-1100 aluminum were tested. Some specimens were welded and some were tested with applied bending stress. No pitting or other microstructural corrosion was detected, but noticeable changes occurred in the surface appearance, especially with aluminum and copper.

The reaction of fluorine with copper and iron was studied within a very wide temperature and pressure range [300]. Under medium fluorine pressures the formation of continuous films was observed. With low fluorine pressures and at relatively high

Table 36: Rate of corrosion of metals in gaseous fluorine.

Data source: [295]

temperatures, a process of nucleation and growth of fluorides took place. The presence of traces of oxygen in the gas phase can have a strong influence on the nature of the products formed.

The composition and thickness of fluoride films that formed upon exposure of various metals to F_2/N_2 at room temperature were studied using X-ray photoelectron and Auger electron spectroscopy (AES) [301]. Depth profiles were obtained using AES with argon ion sputtering. The metals studied included low carbon steel, 302 stainless steel, copper, and brass (70% Cu/30% Zn). Samples treated in 0.12% F_2/N_2 displayed small amounts of surface fluorine, primarily in the form of fluorinated hydrocarbons rather than metal fluorides. In contrast, exposure to 25% F_2 produced thicker films, consisting mainly of metal fluorides with some metal oxides. Fluorine did not seem to penetrate beyond the native oxide initially present on the metal foil surface. Iron fluorides formed on low carbon steel and copper fluorides formed on copper. Surprisingly, iron fluorides preferentially formed on stainless steel, and zinc fluorides preferentially formed on brass. These results provided new insight into the passivation of metals by F_2 but also raised new questions.

4.1.2.1 Ignition Temperature of Metals in Fluorine Gas

The ignition temperature of metals in gaseous fluorine was measured in a high-pressure bomb rated for an operating pressure of 20.67 MPa = 204 atm at room temperature [302]. This technique may be suitable as a method for the evaluation of newly developed materials of construction for fluorine service. The attached manifold allowed the bomb to be alternately evacuated, filled with fluorine, or purged with nitrogen. The metal under investigation had to be available in wire form, so that it could be coiled to a spiral and connected to the terminals of an electric feed-through like the filament in a light bulb. The diameter and length of various wire coils are summarized in Table 37, sorted by increasing ignition temperature.

Table 37: Ignition of metals in fluorine gas.

Material tested	Sample diameter	Sample length	Average ignition temperature	
	mm	mm	°C	K
Al	0.25	100	Melted before it ignited	
Mo	0.8	100–125	205	478
W	0.38	50–125	283	556
Monel	0.25	100–150	396	669
Fe	0.35	150–200	672	945
Stainless steel	0.51	150–200	681	954
Cu	0.28	300	692	965
Ni	0.38	150–180	1153	1426

Data source: [302]

The filament was gradually heated by an electric current until ignition took place. After the test the metal wires were coated with black fluoride. If the temperature function of the resistance of the metal under investigation is known, the ignition temperature could be derived from the resistance at the moment of ignition. Following the test, excess fluorine had to be vented into a fluorine neutralization/absorption unit like those described in [303, 304] using the reaction with activated charcoal.

Attempts have been made to correlate the ignition temperature results via an ARRHENIUS function similar to one used for homogeneous gas reactions:

$$\frac{1}{t} = Ae^{-\frac{E_{\text{act}}}{RT}}$$

where t is time to ignition, T is the absolute temperature, and E_{act} is the activation energy.

When the time to ignition was plotted $\log 1/t$ versus $1/T$, a straight line was obtained and the activation energy of the ignition reaction could be derived from the slope of this line. Looking at the results summarized in Table 37, one can see that nickel is very suitable for construction of components that are exposed to fluorine at higher temperatures. Nickel owes this desirable property to the high sublimation temperature of its fluoride. See also Kadri et al. [305].

A study of the ignition of metals in gaseous fluorine used cylindrical samples that were machined to a diameter of 3 mm for a length of 40 mm and heated by passing an electric current through them [306]. When samples were heated by direct passage of an electric current at pressures near 0.2 MPa, it was observed that titanium, molybdenum, tungsten–niobium alloy, nickel, iron, carbon steel, and stainless steel in gaseous fluorine ignited through a thermal explosion mechanism, whereas copper, its alloys, and aluminum ignited when the melting point of the fluoride film was reached. Comparing the ignition temperature data for different metals, it was concluded that compact metallic materials ignite in fluorine by a thermal Semenov–Frank–Kamenetskii mechanism. Another pattern was observed in the ignition of copper and its alloys. The fluoride films formed on the surface of these materials when they are oxidized at high temperatures in fluorine have high protective properties because the process proceeds at a low rate and with a parabolic kinetic dependence. At temperatures below that for ignition, the interaction of steels and nickel with fluorine is characterized by linear oxidation kinetics. The transition from linear to parabolic kinetics is determined by the enrichment of the fluoride film in iron trifluoride and, in the case of nickel, by the coarsening of NiF_2 crystals in the film. The ignition of the refractory metals, nickel, and alloys based on iron in fluorine at pressures near 0.2 MPa proceeds by a thermal Semenov mechanism, whereas copper and its alloys ignite through a Friedman–Macek mechanism.

4.1.3 Exposure of Copper to Gaseous Fluorine

Another metal suitable for fluorine use is copper. The corrosion of copper by fluorine gas at 703 to 923 K (430 to 650 °C) and the rate of fluorine consumption by a freshly cleaned copper foil at a fluorine pressure of 26.7 kPa = 200 mm Hg was measured in order to derive a kinetic rate equation.

The reaction between fluorine gas and copper metal has been studied at 723 K (450 °C) and pressures from 1.3 to 17.3 kPa (10 to 130 mm Hg) [307, 308]. The reaction was pressure dependent and followed the logarithmic law

$$y = K \log(at + c) + C$$

The logarithmic rate constant K varied with pressure according to the equation

$$\log K = m \log P + 6.11439$$

where m is equal to 0.781. Analysis of the corrosion film yielded an F/Cu ratio of 1.11. A reaction mechanism was postulated, and from the evidence presented, it was proposed that fluorine is the migrating species in the diffusion reaction.

It became quickly obvious that this is not a purely chemical reaction, but the global rate is diffusion-limited by the rate of diffusion of fluorine through the CuF_2 layer formed on the surface. When the logarithm of the reaction rate was plotted versus the reciprocal absolute temperature, a change of slope was noticed at 813 K (540 °C), which indicated that two different mechanisms were at work. However, the slope of the curve decreased instead of increasing above 813 K. Other investigators doing similar experiments also had difficulties interpreting their experimental results. The reaction has been investigated under high vacuum conditions between room temperature and 523 K (250 °C), and at pressures between 0.8 and 8 kPa (6 mm and 60 mm Hg) [242]. The equation

$$x = x_0 \log_{10}(1 + at) + b$$

was obeyed, where x is the thickness of the corrosion film at time t , and x_0 , a , and b are constants. The experimental data showed that the reaction cannot be controlled by a simple diffusive process. The most satisfactory interpretation was that it may be due to random cracking of the protective film, but this does not explain the phenomenon precisely.

Copper powder reacted with fluorine at 773 K (500 °C), but the conversion to copper(II) fluoride was only 53% because the fluoride coating prevented further reaction [289].

In preparation for fluorine exposure tests, copper coupons were treated with clean, concentrated nitric acid for 1 s to obtain a bright, shiny surface. The sample exposed at 823 K = 550 °C showed a film that was too thin to measure accurately [297]. Samples of copper exposed at 923 and 1023 K (650 and 750 °C) showed the typical dull, brick-red corrosion layer, which appeared to be fairly adherent. Agreement between the corrosion rates obtained by use of weight change data and those obtained using

film thickness data was surprisingly good considering the uncertainty of the nature of the corrosion product. See also Steindler and Vogel [309].

4.1.4 Exposure of Nickel to Gaseous Fluorine

Looking at the results of time to ignition tests summarized in Table 37, one can see that nickel is very suitable for construction of components that are exposed to fluorine at higher temperatures. Nickel owes this desirable property to the high sublimation temperature of its fluoride.

Similar tests for the reaction between nickel and fluorine were performed using a radioactive tracer technique with radioactive nickel at 873 to 973 K (600 to 700 °C) [310–312]. Again, it was found that the overall rate depends on the rate of diffusion of fluorine through the NiF_2 surface layer. This is in contrast to the growth of oxide films with nickel where it was assumed that nickel ions migrate through the oxide scale to react with more oxygen on the surface.

Nickel difluoride NiF_2 is formed in the fluorination of metallic nickel between 813 and 1083 K (540 and 810 °C) [313]. The kinetics of the formation of the fluoride film within the investigated temperature interval are dominated by a diffusion mechanism. The activation energy of the process of formation of NiF_2 was 247 kJ/mol (59.0 kcal/mol) at medium temperatures (813–873 K = 540–600 °C) and 77.4 kJ/mol (18.5 kcal/mol) at high temperatures (993–1083 K = 720–810 °C). The NiF_2 film was stable to hydrolysis up to temperatures close to 683 K (410 °C). A similar study was done on copper with gaseous fluorine [314].

The film thickness obtained on exposure of nickel to fluorine at 823 K = 550 °C was too small to measure and the data were obtained only from the weight gain of the coupon. Samples exposed at 923 and 1023 K (650 and 750 °C) showed films of measurable thickness and the corrosion rates were calculated from both of these observations [297].

The crystal structures of protective films of FeF_2 and NiF_2 formed on Fe and Ni surfaces in NF_3 and SF_6 at 1473 K (750 °C) were examined by electron diffraction [315]. In NF_3 at 473–573 K (200–300 °C), a phase transformation of $\text{FeF}_2 \rightarrow \text{FeF}_3$ was observed.

The resistance of nickel and its alloys, particularly Monel, against fluorine and HF is fairly good at temperatures up to 900 K [316, 317]. During the attack of nickel–chromium alloys by fluorine between 1000 and 1300 K, an inner fluorination mechanism similarly to the inner oxidation is taking place.

4.1.5 Exposure of Iron to Gaseous Fluorine

Iron is rarely used in the pure state, but it is the main constituent of all steels. The effect of temperature and pressure on the reaction of fluorine gas on solid iron samples was studied at various pressures up to 26.7 kPa (200 mm Hg) over the temperature range of 498 to 798 K (225 to 525 °C) [318, 319]. The reaction was found to follow a logarithmic rate law, and logarithmic rate constants were calculated. The probable mechanism of

film growth is the movement of fluorine through defects in the fluoride film to the iron surface.

The reaction of fluorine with iron has been considered as a method for fluorine removal from waste gas streams [320]. Laboratory tests have been conducted to evaluate the fluorine–iron reaction as a possible method of chemically scrubbing fluorine from waste gas mixtures to be vented to the atmosphere. Iron in the form of coarse steel wool packed into a cylindrical nickel reactor was found to consume nearly all the fluorine from fluorine–oxygen and fluorine–nitrogen mixtures containing from 0.5 to 100% fluorine. External heat to the reactor was required to ensure complete reaction at the lower fluorine concentrations. Gaseous fluorides found in the emitted reaction products ranged from less than 1 to 15 ppm. Gaseous products from the reactions of fluorine–oxygen mixtures with iron were less than 3% of the volume of gases fed into the reactor. The exit gas was essentially nitrogen, which indicated that oxygen had also reacted with the iron. No toxic gaseous products were emitted, and the solid products were non-volatile and totally contained the fluorine for long-term storage or disposal in a landfill.

4.1.6 Exposure of Titanium to Gaseous Fluorine

Titanium powder reacted appreciably with fluorine above $423\text{ K} = 150^\circ\text{C}$, the vigor of the reaction depending on the size of the metal particles [321]. Conversion was complete above $473\text{ K} = 200^\circ\text{C}$. Titanium(IV) fluoride could be synthesized by fluorination of massive titanium, preheated to $523\text{ K} = 350^\circ\text{C}$ in the reactor.

Because titanium may ignite even in liquid oxygen or dinitrogen tetroxide if freshly fractured surfaces are exposed to an oxidizer, this concern about accidental ignition is heightened when exposing titanium and titanium alloys to fluorine (liquid or gas). If titanium tubing or tanks are used for fluorine service, they must not be bent or vibrated while exposed to the oxidizer. Vibrations can be induced externally (launch vibration, road transport vibration) or internally (water hammer, fluttering valves, resonant cavities, combustion instabilities in the rocket chamber).

The resistance of titanium in water-free liquid fluorine at lower temperatures is $<0.3\text{ mm/year}$, which is comparable with that of nickel and Monel [316, 317]. The rate of corrosion of titanium in gaseous fluorine at 377 K is only 0.0082 mm/year .

4.1.7 Exposure of Zinc to Gaseous Fluorine

Zinc is not a metal one would want to use for construction of fluorine equipment, but zinc is a constituent of brass and brass was considered for use with fluorine, although it is not recommended. The reaction between zinc metal and fluorine gas can be described by a parabolic rate law [322]. This reaction is both temperature and pressure dependent. Simple kinetics are complicated by the noticeable vaporization rate for zinc at temperatures above 573 K (300°C).

4.1.8 Exposure of Refractory Metals to Gaseous Fluorine

Fluorine reacted with zirconium powder above $463\text{ K} = 190^\circ\text{C}$. Fluoride coating of metal powder prevented complete conversion to zirconium fluoride. The maximum conversion obtained was about 90% at $693\text{ K} = 420^\circ\text{C}$. At higher temperatures some product was lost owing to sublimation.

In spite of their limited resistance against fluorine and HF, very pure molybdenum and tungsten are employed as construction materials in the design of rocket engines because of their good strength at high temperatures if they are exposed to fluorine–hydrogen or fluorine–hydrazine flames [316, 317]. Lanthanum borides and calcium borides intended as coatings for the inside of combustion chambers were exposed to fluorine–hydrazine flames but were attacked only a little at temperatures between 1400 and 1800 K; they were superior to all special grade alloys.

4.1.9 Exposure of Aluminum to Gaseous Fluorine

Aluminum and duralumin (Al–Cu alloy system, or Al-2000 series) are resistant against fluorine and HF up to 600 and 700 K respectively [316]. The resistance of nickel and its alloys, particularly Monel, against fluorine and HF is fairly good up to 900 and 800 K. During the attack of nickel–chromium alloys by fluorine between 1000 and 1300 K, an inner fluorination appears to take place similar to the inner oxidation by oxygen diffusion.

4.1.10 Exposure of Silver to Gaseous Fluorine

Silver is a constituent of most brazing alloys. It is important to find a brazing alloy that is compatible with fluorine. The effect of temperature and pressure on the kinetics of the reaction of fluorine with silver were studied over a temperature range from 298 to 573 K (25 to 300°C), and the reaction was measured at fluorine pressures of 6.7–80 kPa (50–600 mm Hg) [323, 324]. The reaction was pressure dependent. Three reaction products were identified: silver subfluoride (Ag_2F), silver monofluoride (AgF), and silver difluoride (AgF_2). No simple rate law could describe the growth of film thickness data over the entire time interval of the reaction.

Silver solder may be used to join two or more members. Silver is not very resistive to fluorine attack, but the addition of copper improves its resistance, whereas cadmium or lead lowers the resistance to attack, although the workability of the solder is increased.

4.2 Behavior of Metals in Contact with Liquid Fluorine

In general, all materials that are proven to be compatible with gaseous fluorine are also suitable for service with liquid fluorine. When selecting metals for cryogenic liquid fluorine service, the melting point and volatility of the formed fluoride no longer has the

same importance as when selecting materials for high temperature service. However, the potential solubility of fluorides in liquid fluorine becomes a determining factor. The rates of corrosion of various metals in liquid fluorine were reported ([292]). This section on the compatibility of metallic materials of construction with liquid fluorine is subdivided such that publications dealing with more than one metal, more general overviews, are discussed first. The last several sections deal with specific metals, one at a time.

One must also keep in mind that equipment for handling of liquid fluorine is not always kept at the cryogenic temperatures of liquid fluorine, but may alternate between cryogenic and room temperature, resulting in occasional rapid temperature transients, thermal stresses, and flaking of the protective layer of fluorides. Other materials may be chemically compatible, but become embrittled at cryogenic temperatures (even in the absence of fluorine) and must be eliminated from further consideration. See also [325].

Corrosion tests of 25 metals and alloys by liquid and gaseous fluorine were performed at 77 K (−320 °F) and exposure times ranged from 5 h to 3 days [326]. Exposures to gaseous fluorine were made at approximately 300, 477, 644, and 811 K (80, 400, 700, and 1000 °F). Exposure times were generally 5, 24, and 120 h. Several specimens were also exposed to gaseous fluorine at elevated pressures and temperatures for 24 h. Selected specimens were cross-sectioned and photomicrographs taken to study the passivating fluoride film. Results of the 5-h tests indicated that all tested materials, except tantalum, may be exposed to fluorine at temperatures up to 477 K (400 °F) without exceeding a corrosion rate of 0.0005 in/h. This arbitrarily chosen rate was not intended to signify acceptability. It was equivalent to 4.4 in/year, which is an extremely high corrosion rate under normal circumstances, but not excessive when exposure for only a few hours is required. It must be understood that extrapolation of the results obtained from very short exposures to long time service, such as a year, is not reliable. In general, the corrosion rates tend to decrease as the exposure period is extended. Tests of materials at elevated pressures indicated that corrosion rates were generally higher than specimens exposed to the same temperatures at atmospheric pressure. Microscopic examination of selected specimens showed that materials such as Monel and nickel formed a relatively uniform passivating film at elevated temperatures. Aluminum 1100, however, showed indication of deep, non-uniform penetration.

Studies were made to determine the compatibility and resistance to corrosion of various metals with liquid F_2 at 77 K (−320 °F) [327]. Metals tested included various alloys of Al, stainless and high strength steel, Ti, Cu, Monel, Ni, and Mg. It was found that the total corrosion of Ti that had been exposed to liquid F_2 was independent of time for periods up to 2 weeks. The corrosion of Mg increased up to 1 day, but longer exposures up to 2 weeks produced no further corrosion. Increased corrosion of metals by F_2 contaminated with water does not occur at liquid F_2 temperatures, but takes place in the gas phase while the system is warming. F_2 that had been liquefied in glass cells was found to contain solid material leached from the glass. When new facilities

are placed into service for the first time, pretreatment with F_2 gas is recommended as it can burn off surface contamination, which might prove a dangerous source of ignition during liquid exposure. Abrading metal surfaces under liquid F_2 with wire bristles caused no apparent increase in corrosion rate.

In studies of reactions of liquid fluorine and its contaminants on metal surfaces, the formation of fluoride films was measured during immersion of tensile specimens [66]. A method of preparing contaminant-free fluorine and verifying its purity by IR analysis was developed to ensure that the results are reproducible. No violent liquid phase reactions between fluorine and metals were observed but gas phase reactions occurred during warmup. Small weight changes in metal specimens immersed in liquid fluorine for 15 and 75 min were noted. Exposure of hydrocarbon films on metals to F_2 formed carbon deposits, whereas exposure to ClF_3 or $ClF_3 + F_2$ left fluorocarbon films behind. No detectable fluoride films formed on Al specimens using electron diffraction techniques. At low temperatures gaseous fluorine formed films of less than 200 Å on metal powders with initially rapid film formation tapering off to a negligible rate after 1 day. Metal powders absorbed gaseous fluorine at 100 K (-279°F). Metal tensile specimens exposed to liquid fluorine for 1 year corroded less than one thousandths of an inch. These specimens had essentially the same tensile properties as similar ones exposed to liquid nitrogen.

The rate of penetration of corrosion into material samples immersed in liquid fluorine was measured for durations of up to 1 year [328–330]. The results are summarized in Table 38, but may not be very reliable because they show substantial scatter.

Table 38: Corrosion of passivated metal samples in liquid fluorine.

Metal	Depth of penetration, micrometer, after					
	15 min	75 min	6 h	1 week	2 weeks	1 year ^a
Nickel			0.2		0.2	0.08
Monel			0.5	0.3	0.4	0.08
CRES-304	0.03	0.05	0.05	0.1	0.2	0.08
CRES-430						1.6
Stainless steel 420	0.05		0.2	0.2	0.2	
Steel Armco 15-7PH Mo					0.08	0.03
Copper	0.03	0.05	0.2		0.4	0.08
Magnesium HK31	0.2	0.03	0.5		0.8	17.1
Magnesium AZ31	0.08	0.1	0.5		1.0	8.7
Aluminum 1100	0.03	0.1	1.3	0.03	1.1	5.3
Aluminum 6061	0.03	0.03	0.1	0.2	0.8	4.7
Titanium A 110 AT	1.1	1.0	0.6		1.1	7.1
Titanium C 120 AV			0.3	0.5	1.0	5.8

^a The values after 1 year are unreliable because there may have been contamination by moisture and condensation from ambient air.

Data source: [328]

From Table 38 one can learn that with nickel, Monel, copper, CRES-304, CRES-420, and Armco iron 15-7, the depth of penetration remains below $1\text{ }\mu\text{m}$, even after long-term exposure. For the time frame from 6 h to 2 weeks both passivated and non-passivated specimens gave the same results. Also, mechanically stressed metal coupons did not show a fundamentally different behavior. In another series of tests, the fluorine absorption by metal powders was measured gasometrically and the thickness of the fluoride passivation layer calculated theoretically. In the case of nickel, the predicted thickness was 1.2 nm .

Impurities in the liquid fluorine may affect the rate of corrosion significantly [331]. The presence of HF in fluorine increases corrosion of metals markedly. The HF is usually generated in fluorine systems from the reaction of atmospheric moisture or moisture in the system with fluorine. Contaminants in fluorine other than HF do not present corrosion or safety problems. Cleanliness of a fluorine system must be emphasized because contaminants cannot be removed from the apparatus by passivation procedures. Most corrosion in a liquid fluorine system occurs during the first hour of exposure.

The results discussed here so far covered only the exposure to gaseous or liquid fluorine, whereas in real life the situation may alternate between these two conditions. In a study of the behavior of various metals under more practical conditions of exposure, the samples were exposed in a hermetically closed system alternately for 12 h to liquid nitrogen temperature, causing the fluorine to condense on the samples, and subsequently allowed to thaw and warm to room temperature, where they were kept for another 12 h [332]. Metals tested in this series included Ni, Monel, Al3 S-O, Al52 S-O, CRES-347, CRES-321, as well as a brass with a low lead content (0.96% Pb). The test series was continued for 2.5 to 3.5 months and the weight change of the samples was recorded. It was concluded that all materials tested in this series were suitable for alternating gaseous-liquid fluorine service.

Liquid fluorine is not a very conductive electrolyte. The remaining conductivity is mostly due to contaminants, mainly HF. The galvanic corrosion of eight different metals in contact with each other was measured in liquid fluorine for 21 days at 77 K ($-196\text{ }^{\circ}\text{C}$) [333]. There was evidence of pitting on Al-2014-T6 and silver coupons. The electrode potentials of several metals (Al-1100, soft Cu) versus Pt as a reference electrode were measured and arranged in a sequence of increasing electronegativity.

The mechanisms of corrosion in liquid fluorine and in alternating liquid-gaseous environments are not fundamentally different. In general, all materials proven for liquid fluorine service can also be used for alternating liquid-gaseous conditions. Polished cross-sections of mounted exposed metal specimens were prepared in an attempt to see the thickness of the fluoride layer, such that corrosive action could be examined in cross section, but even at $\times 250$ magnification, the passivation layer could not be seen.

The effect of liquid fluorine immersion on the mechanical properties of several sheet alloys (AM350, ASM6434, Inconel X, AISI 301, AISI 304L, Al-2014-T6, Al-6061-

T6, Al-7075, Ti-6Al-4V) was investigated [334, 335]. The smooth and notched tensile strength and the elongation properties of steel, nickel, aluminum, and titanium alloys were determined in liquid-nitrogen and liquid-fluorine environments at 77 K (-320°F). The smooth specimens were loaded to a stress value equal to 90% of the yield strength of the material at a temperature of 77 K (-320°F = liquid-nitrogen boiling temperature). This load was maintained for 2h. Possible deterioration in the presence of fluorine and high stresses was detected by comparing the properties of alloys exposed to the two fluids at 77 K (-320°F). The as-received fluorine contained contaminants typically found in commercial fluorine. The results of tests in liquid fluorine indicated possible degradation of the mechanical properties of the sheet alloys. Following 2-h exposure, the decrease in tensile strength ranged from negligible to a maximum reduction of approximately 11%. Elongation showed similar trends. The sharp-notch strengths appeared to be unaffected by the liquid fluorine. Variations in test results and surface appearance could have been due to varying amounts of contaminants in the liquid fluorine, fluctuating from one batch to another. There was no evidence of ignition on any of the specimens that were fractured in the liquid fluorine environment. Where high thermal conductivity is essential, Al-6061 is a possible material of construction.

The compatibility of various alloys with liquid fluorine and FLOX under stress [336] and with gaseous FLOX under stress [337] was assessed in static immersion tests [338].

The rates of corrosion of Ti-6Al-4V and Al-2219-T87 in liquid fluorine and Ti-6Al-4V in FLOX (12% F_2) at 77 K were determined by neutron activation analysis, radioactive tracer techniques, and atomic absorption spectroscopy to analyze for leached metals [339, 340]. The rates of corrosion were very dependent on the HF present as a contaminant in fluorine. The results of test durations up to 100 h were used to calculate reaction rate constants and to predict corrosion over a time span of several years.

For a short time, converting a VANGUARD first stage or ATLAS [341–343] or THOR or SATURN S-IC [344] launch vehicle to operation on FLOX instead of LOX was considered, in order to gain more payload capability. In this case, compatibility of FLOX with existing materials of construction was a difficult issue, and that was most likely the main reason why these conversions never got to fly. The results of compatibility testing of ATLAS relief valve, boil-off valve, airborne instrumentation, fill and drain valve, staging valve, and miscellaneous components with 50% FLOX made it obvious that major redesigns would be necessary [345].

In one test series, the following materials in tensile test dog bone coupon shapes were immersed in 20% or 30% FLOX for 200 h and compared with controls immersed in LN_2 for the same duration [346]:

1. stressed CRES-301, plain or spot welded or fusion welded
2. stressed K-Monel, plain or fusion welded
3. stressed fusion butt weld between CRES-321 and nickel A
4. stressed Al-6061-T6
